Abstract

A common bias in cultural transmission is to copy whoever appears more successful. This success bias only depends on the performance of the role-model. Because success may be difficult to estimate, it has been suggested that individuals may indirectly estimate success by using prestige as a proxy for success. However, prestige can be defined in different ways: it can reflect performance in another, possibly related, task; but it can also reflect overall influence of the role-model, irrespective of performance. Here, we model prestige bias as a combination of indirect success bias and influence bias, the latter meaning that the choice of a role-model depends on the number of individuals that have already copied from that role-model. We analyze the effect of prestige on cultural evolutionary dynamics using mathematical analysis and stochastic simulations. We find analytic approximations to the stochastic role-model choice process, which facilitate further mathematical analysis and reduce the computational complexity of simulations. We validate these approximations and demonstrate their robustness to model assumptions. We also find approximations to the fixation probability and the fixation time of an invading cultural trait, in both constant and changing environments. These approximations are similar to Kimura's approximations for population-genetic models. These similarities show that indirect success bias effectively plays the role of natural selection, whereas influence bias effectively plays the role of genetic drift. Influence bias also accelerates the evolutionary dynamics, as can be expected in a *rich-getting-richer* process. Our model extends the literature that describes and analyses cultural transmission, especially in human societies where social media is popular and thus influence bias may be expected. Further work is needed to test if this model could explain and predict various phenomena in cultural evolution.

30 Introduction

In cultural transmission, individuals transmit cultural traits (i.e., behaviors, beliefs, norms) to one another, typically by learning and demonstrating (Cavalli-Sforza and Feldman, 1981). Examples for cultural traits in humans are norms, preferences, tools, ideas, and language, potentially transmitted verbally and/or by observations (Creanza et al., 2017). Although cultural transmission is common in humans, it is also observed in other animals, e.g. chimpanzees (Horner et al., 2010; Kendal et al., 2015), dolphins and whales (Whitehead, 2017), elephants (McComb et al., 2001), and even flies (Battesti et al., 2012) and fish (Truskanov et al., 2020).

Cultural transmission may combine vertical transmission, in which parents transmit to their offspring; oblique transmission, in which adults (teachers, leaders, and even strangers) transmit to unrelated offspring; and horizontal transmission, in which peers from the same age cohort transmit to one another (Cavalli-Sforza and Feldman, 1981; Creanza et al., 2017). It has been demonstrated that non-vertical cultural transmission can maintain maladaptive traits, which can be beneficial in changing environments (Ram et al., 2018).

Transmission biases may cause a cultural trait to have a disproportionate probability to be transmitted compared to its frequency in the population. *Success bias* occurs when individuals prefer to copy from role models that demonstrate success in some activity, such as fishing, growing yams, using medicinal plants (Henrich and Broesch, 2011), or hunting (Mesoudi and O'Brien, 2008), and it can increase the probability of learning a successful trait (Borofsky and Feldman, 2022). Indeed, in a tournament between learning strategies conducted by Rendell et al. (2010), most winner strategies included a mixture of success-biased social learning and individual learning, implying that success-biased learning is a good strategy, but that by itself it is not enough to best other strategies, even when success is measured accurately.

Boyd and Richerson (1988, Ch. 5) have suggested that the evaluation of success can be divided to three categories: *direct bias*, *indirect bias* and *frequency-dependent bias*. A direct bias occurs when one phenotype is more attractive than other phenotypes, and is evaluated by *directly* testing the trait. For example, an individual observing a ping-pong match can attempt the observed paddle grips to determine which grip is better. A frequency-dependent bias occurs when the probability to copy a phenotype is higher or lower than the frequency of the phenotype among demonstrators. For example, suppose the common paddle grip is used by 60% of the demonstrators; if the this grip is adopted by 80% of copiers, then transmission is under positive frequency bias, also called *conformity*; if it is adopted by 40% of copiers, then transmission is under negative frequency bias, or *non-conformity* (Molleman et al., 2013). The effects of conformity and non-conformity on cultural evolution have been studied with both models (Denton et al., 2020, 2021, 2022) and experiments (Aljadeff et al., 2020). An indirect bias occurs when an individual uses one phenotype to determine the attractiveness of another phenotype. For example, an observer may copy the paddle grip of the ping-pong player who scored more points in the match, thus indirectly evaluating the grip by the points scored. This, however, may cause mismatches between the copied trait and the rest of the cultural or genetic repertoire of the

68 individual (Kolodny et al., 2022). Furthermore, Boyd and Richerson (1988, Ch. 8) have suggested
that maladaptive traits may spread widely in a population if indirect biases are strong enough by a
70 runaway process caused by a cultural equivalent of sexual selection (Andersson, 1994). For example,
Cohen et al. (2021) have shown that helping behaviors can evolve due to horizontal transmission bias
72 even without any benefit to the recipient, or when the benefit is much larger than the cost.

Henrich and Broesch (2011) have studied such indirect success biases, which they call cross-domain
74 success bias or *prestige bias* (e.g., great fishermen may be chosen as role-models for growing yams).
They have suggested that such biases, over generations, can lead to cultural adaptations, and that
76 although prestige can lead to maladaptive traits spreading in the population, it can also accelerate the
spread of adaptive traits. Boyd and Richerson (1988, Ch. 8) and Fogarty et al. (2017) have suggested
78 that prestige biases are probably more common in humans than success biases, and prestige is often
mentioned in the cultural evolution literature, however there are few models of prestige bias.

80 A broader definition of prestige is the “widespread respect and admiration felt for someone or something
on the basis of a perception of their achievements or quality” (New Oxford American Dictionary).
82 Indeed, Chudek et al. (2012) have defined prestige bias as “a tendency to learn from individuals to
whom others have preferentially attended, learned or deferred”, and demonstrated its occurrence in in
84 3-4 year old children. To distinguish this form of indirect bias from other definitions of prestige, we
call it *influence bias*. This is an important distinction, as influence is a context-based bias, rather than
86 a content-based bias: it does not depend on the phenotype itself but rather on the number of copiers
that already copied each role-model, which may be easier and more accurate to estimate compared
88 to success. Influence bias differs from frequency biases such as conformity, which depend on the
frequency of a trait in the population or in a sample of role-models, rather than the social dynamics
90 of copying. Henrich and Gil-White (2001) define prestige in a similar manner, and their definition for
influence bias is similar to ours.

92 In contemporary human society, social media makes it especially easy to estimate the social and
cultural influence individuals have over others, and therefore can have an effect on decision making.
94 Online social networks such as *Facebook* and *Instagram* are known to affect the influence of individuals
(Anagnostopoulos et al., 2008; Diga and Kelleher, 2009; Peng et al., 2018), and specific marketing
96 practices were invented to capitalize on this effect (Lee et al., 2012).

In the following, we develop a stochastic model of cultural transmission with prestige bias. In our
98 model, prestige combines both cross-domain indirect success bias and influence bias. We develop
analytic approximations for this model and analyze its dynamics. We find approximations for the
100 probability and time for fixation of a ‘successful’ phenotype (i.e., that is favored by success bias).
Comparing these approximations to Kimura’s approximations for the fixation of a favorable allele
102 (Kimura, 1962; Kimura and Ohta, 1969), we demonstrate that success and influence bias play the role
of natural selection and genetic drift, respectively.

104 Models

We begin with a continuous trait model with indirect bias suggested by Boyd and Richerson (1988),
 106 develop an extension with influence bias, and then develop a model with a dichotomous trait. We
 implemented our stochastic models and approximations, performed statistical analyses, and produced
 108 figures using Python (Van Rossum et al., 2007) with NumPy (Van Der Walt et al., 2011) and Matplotlib
 (Hunter, 2007). Source code is available at <https://github.com/yoavram-lab/PrestigeBias>.

110 Continuous trait

We follow the model of Boyd and Richerson (1988), assuming only oblique transmission of the trait
 112 and omitting the indirect trait in order to reduce model complexity. We consider a population of N
 individuals, described by a single trait with a continuous value. Each generation, N naive individuals,
 114 or copiers, choose an individual from the previous generation, or role-models, from which they will
 copy their trait. Similar to a Wright-Fisher model, we assume non-overlapping generations such that
 116 the entire population is replaced in each generation. The population at time t can be described by
 $\mathbf{A}(t) = (A_1(t), \dots, A_N(t))$ where $A_i(t)$ is trait value of individual i at time t . We assume the initial
 118 population is drawn from a standard normal distribution, $\mathbf{A}(0) \sim N(0, 1)$. Cultural transmission is
 modeled by a function F such that

$$120 \quad A_i(t+1) = F_i(\mathbf{A}(t)) . \quad (1)$$

Success bias. Boyd and Richerson (1988, Ch. 8, p. 247-249) describe a blended transmission algo-
 122 rithm by defining F as a weighted average of the traits of all role-models,

$$F_i(\mathbf{A}) = \sum_{j=1}^N G_{i,j} \cdot A_{i,j} , \quad (2)$$

124 where $G_{i,j}$ is the success bias of role-model j in the eyes of copier i ,

$$G_{i,j} = \frac{\beta(A_{i,j})}{\sum_{k=1}^N \beta(A_{i,k})} , \quad (3)$$

126 $A_{i,j}$ is the absolute trait value copier i estimates for role-model j with some error $e_i \sim N(0, \eta^2)$,

$$A_{i,j} = A_j + e_i, \quad (4)$$

128 and $\beta(\cdot)$ is the bias function that quantifies the success bias of a role-model,

$$\beta(A_{i,j}) = b \cdot \exp\left(-\frac{(A_{i,j} - \hat{A})^2}{2J}\right) , \quad (5)$$

130 with \hat{A} as the arbitrary optimal trait value, and J and b as parameters that control the bias strength.
 Therefore, $G_{i,j}$ is a relative success score that copier i assigns to role-model j , equivalent to relative
 132 fitness in evolutionary-genetic transmission models.

Boyd and Richerson (1988) note that the deterministic blended transmission algorithm they use has
 134 alternatives. We thus develop a similar stochastic model with transmission from a single random
 role-model. Instead of eq. (2), we define the transmission function F as a random variable with its
 136 distribution given by

$$\Pr(F_i(\mathbf{A}) = A_j) = G_{i,j} , \quad (6)$$

138 such that $G_{i,j}$ gives the probability of copier i to choose to copy the trait of role-model j .

Influence bias. Here we introduce a new element to the model. We assume that in each generation,
 140 copiers choose their role-models one by one. We denote $K_{i,j}$ as the number of copiers that chose
 role-model j after copier i chose a role-model. Thus, i out of N copiers already chose a role-model,
 142 $\sum_{j=1}^N K_{i,j} = i$, and there are $N - i$ copiers that have yet to choose a role-model. The stochastic process
 of role-model choice,

$$\{\mathbf{K}_i = (K_{i,1}, \dots, K_{i,N})\}_{i=1}^N , \quad (7)$$

is described by the recurrence equation

$$K_{i,j} = K_{i-1,j} + S_{i,j}, \quad i, j = 1, 2, \dots, N , \quad (8)$$

where $S_{i,j} = 1$ if the i -th copier chose role-model j and 0 otherwise, and the initial state is $K_{0,j} =$
 148 0.

Following eq. (6), the probability that the i -th copier chose role-model j is given by the prestige of
 150 role-model j in the eyes of copier i ,

$$\Pr(S_{i,j} = 1 \mid S_{1,j}, S_{2,j}, \dots, S_{i-1,j}) = G_{i,j} . \quad (9)$$

152 The prestige $G_{i,j}$ of role-model j in the eyes of copier i is determined by success—the estimated biased
 trait value $\beta(A_{i,j})$ —and influence—the number of copiers that chose role-model j before copier i , $K_{i-1,j}$,
 154 replacing eq. (3) of Boyd and Richerson (1988) with

$$G_{i,j} = \frac{\alpha_{ij} \cdot \beta(A_{i,j}) + (1 - \alpha_{ij}) \cdot K_{i-1,j}}{W_i} . \quad (10)$$

156 Here, the bias weight α_{ij} is a characteristic of the interaction of role-model j with copier i that
 determines the relative significance of direct success vs. influence in the role-model's overall prestige
 158 in the eyes of the copier.

We assume every individual may evaluate the importance of success and influence differently. Addi-
 160 tionally, we assume every role-model displays his influence and success individually. For example, a
 person with more followers but lack of actual skill may emphasize the number of his followers rather
 162 than his actual skill. We therefore defined $\alpha_{i,j}$ to be the relation between every copier's intrinsic
 significance of estimation, and every role-model's personal emphasis.

164 The trait of role-model j estimated by copier i , $A_{i,j}$, remains as in eq. (4), and W_i is a normalizing factor that sums the numerator over all role-models ($1 \leq j \leq N$) to ensure $\sum_{j=1}^N G_{i,j} = 1$.

166 **Dichotomous trait**

To allow for mathematical analysis of the model, we introduce a simplified version where the trait only has two phenotypes: the optimal phenotype \hat{A} and the sub-optimal phenotype A . All role-models with the same phenotype will contribute to the probability of that phenotype to be transmitted, and thus influence is determined by the number of copiers that have already chosen a role-model with either phenotype. In addition, for simplicity and for easier mathematical analysis, we assume α is homogeneous, such that we have exchangeability between role-models. Therefore, the probability of the i -th copier to copy phenotype A is

$$174 \quad G_{i,A} = \frac{(N - X)\alpha'\beta(A) + K_{i,A}}{i - 1 + (N - X)\alpha'\beta(A) + \alpha'X}, \quad (11)$$

where X is the number of role-models with trait \hat{A} , $K_{i,A}$ is the number of copiers that already chose A when copier i chooses a role-model, $\beta(\hat{A}) = 1$, and $\alpha' = \frac{\alpha}{1-\alpha}$ is the odd ratio of the bias weight. Complementing this, the probability of the i -th copier to copy phenotype \hat{A} is $G_{i,\hat{A}} = 1 - G_{i,A}$. The rest of the details follow the continuous trait model.

Results

180 Our model is defined by two nested stochastic processes. Change over multiple generations is described by the phenotype distribution at each generation, $\{\mathbf{A}(t)\}_t$. The transition from one generation to the next is described by the number of copiers each role-model has after i copiers have chosen a role-model, $\{\mathbf{K}_i\}_{i=1}^N$. We emphasize that the models are nested: $\mathbf{A}(t + 1)$ can be computed from $\mathbf{A}(t)$ by evaluating \mathbf{K}_N . However, the former requires iterating over eqs. (8) and (9). Thus, we sought to find an equivalent stochastic process that has the same joint distribution as \mathbf{K}_N . We found two such approximations, summarized here and explained in detail below. In both we assume either α_j is a trait of role-model j only (contrary to α_{ij} that included the relation with copier i), or a completely homogeneous α .

Generalized binomial approximation. The number of copiers of a specific role-model at each step, $K_{i,j}$, follows the *generalized binomial distribution* (Drezner and Farnum, 1993) and therefore,

(i) the expected number of copiers of role-model j equals its prestige in the eyes of the first copier, multiplied by the total number of copiers, that is, $E[K_{N,j}] = N \cdot G_{1,j}$ if trait estimation error is uniform for all copiers ($e = e_i$ for $i = 1, \dots, N$); and (ii) the expected number of copiers of each role-model equals its relative biased trait value, similar to the role of relative fitness in population-genetic models, that is, $E[K_{N,j}] = \beta(A_j + e)/\bar{\beta}$ if the bias weight is uniform for all role-models ($\alpha = \alpha_j$ for $j = 1, \dots, N$), where $\bar{\beta} = 1/N \sum_{j=1}^N \beta(A_j + e)$ is the population mean estimated trait value.

Dirichlet-Multinomial approximation. The role-model choice process, $\{\mathbf{K}_i\}_{i=1}^N$, is equivalent to a Pólya urn model if trait estimation error is uniform for all copiers ($e = e_i$ for all $i = 1, \dots, N$), meaning there's no meaning for the order of copiers.

Note that here $G_{i,j}$ is only a function of the trait values A_j and the bias weights α_j , as the estimation error is uniform, meaning all copiers are identical.

Generalized binomial distribution

The generalized binomial distribution (GBD) emerges from a series of dependent Bernoulli trials (in contrast to the standard binomial distribution in which trials are independent) and is parameterized by $GBD(n, p, \theta)$ where n is the number of trials, p is the probability of success of the first trial, and θ is the correlation between trials ($\theta = 0$ gives the standard binomial distribution).

Result 1 (Generalized binomial approximation). *The number of copiers of role-model j after i copiers have chosen a role-model follows the GBD, $K_{i,j} \sim GBD(i, \alpha_j \cdot \beta(A_j + e))$ if $e_i = e$ for all role-models $i = 1, \dots, N$.*

Proof. We denote $Q_j(k, i) = P(K_{i,j} = k \mid K_{i-1,j})$ as the probability that exactly k out of i copiers choose role-model j given $K_{i-1,j}$ out of $i-1$ copiers chose role-model j . Using conditional probability and eq. (8),

$$Q_j(k, i) = P_j(S_{i,j} = 1 \mid k-1, i-1) \cdot Q_j(k-1, i-1) + P_j(S_{i,j} = 0 \mid k, i-1) \cdot Q_j(k, i-1), \quad (12)$$

where $S_{i,j} = 1$ when the i -th copier chooses role-model j . Equation (12) is equivalent to eq. (2.1) by Drezner and Farnum (1993), which completes the proof.

This result gives the following two corollaries on the expected number of followers of a given role-model by the end of the role-model choice process. The proof of Corollary 2 is in Appendix A.

Corollary 1. *The expected number of copiers of role-model j after all copiers have chosen a role-model is $E[K_{N,j}] = N \cdot G_{1,j}$, where $G_{1,j}$ is the probability of the first copier to copy role-model j .*

Proof. Drezner and Farnum (1993, eq. (2.3)) show that $E[k] = N \cdot Q_j(1, 1)$ (modified from their notation). $Q_j(1, 1)$ is the initial probability to choose role-model j , before any role-model choices are made. $Q_j(1, 1) = G_{1,j}$ by definition, which completes the proof.

Corollary 2. $E[K_{N,j}] = \alpha_j \cdot \beta(A_j + e) / \overline{\alpha \cdot \beta(A + e)}$, where the averaging in the denominator is over the role-models index, j .

228 The special case where the bias weight is uniform for all role-models ($\alpha = \alpha_j$ for $j = 1, \dots, N$) is interesting, because we can evaluate the expected number of copiers using a linear equation

$$230 \quad E[K_{Nj}] = N \cdot \frac{\alpha \cdot \beta(A_j + e)}{\sum_{m=1}^N \alpha \cdot \beta(A_m + e)} = \beta(A_j + e) \left/ \overline{\beta(A + e)} \right., \quad (13)$$

where the only variable is $A_j + e$, because $\overline{\beta(A + e)}$ is the mean of the distribution of the trait values, modified by some constant parameters of β . We can then denote $L = 1/\overline{\beta(A + e)}$ and write

$$E[K_{Nj}] = L \cdot \beta(A_j + e). \quad (14)$$

234 **Numerical validation.** To validate our results we ran 1,000 simulations of the full model, and compared the results with Corollary 2. We compare the distribution of number of copiers by plotting the histograms of both our simulations results and the expected values based on Corollary 2. We used 236 the average of the 1,000 simulations to eliminate drift errors, as can be seen in Figure 1.

Figure 1: Numerical validation of the GB approximation. The approximation (orange) fits simulation results (blue) well when using 1,000 simulations for both models. Here, population size, $N = 2,000$; bias weight, $\alpha = 0.1$; idea phenotype value, $\hat{A} = 1$; role-model traits $\mathbf{A} \sim N(0, 1)$; success bias value, $\beta(A) = 0.956$.

238 Although basic, Figure 1 shows good fit of the GB approximation. This validation is initial, and the more extensive validations we do on the Dirichlet-Multinomial approximation, because it is what we 240 will use in our analysts.

Dirichlet-Multinomial distribution approximation

242 **Pólya urn model.** This stochastic process consists of N draws from an urn with an initial amount of colored balls of M colors. When a ball is drawn, it is then placed back in the urn together with an additional new ball of the same color. Let $\mathbf{U}_i = \{u_{i,1}, u_{i,2}, \dots, u_{i,M}\}$ where $u_{i,j}$ is the number of balls of the j -th color in the urn after i draws. Let $S_{i,j} = 1$ when drawing a j -colored ball on the i -th draw,

246 and 0 otherwise. The probability that $S_{i,j} = 1$ given \mathbf{U}_{i-1} is

$$P(S_{i,j} = 1 \mid \mathbf{U}_{i-1}) = \frac{u_{i-1,j}}{\sum_{m=1}^M u_{i-1,m}} = \frac{o_j + w_{i-1,j}}{\sum_{m=1}^M o_m + w_{i-1,m}} = \frac{o_j + w_{i-1,j}}{i - 1 + \sum_{m=1}^M o_m}, \quad (15)$$

248 where o_j is the initial number of balls of the color j in the urn, and $w_{i,j}$ is the cumulative number of new balls that were added to the urn after i draws of the color j .

250

Result 2 (Pólya urn model). *The role-model choice process, $\{\mathbf{K}_i\}_{i=1}^N$, is equivalent to a Pólya urn model if both trait estimation error and bias weight are uniform in the population, $e = e_j$ and $\alpha = \alpha_j$ for all $j = 1, \dots, N$.*

254 *Proof.* Denote $\alpha' = \frac{\alpha}{1-\alpha}$ as the bias weight ratio, and $A'_j = A_j + e$. From eq. (10) and because $\sum_{j=1}^N K_{i,j} = i$, we have

$$G_{i,j} = \frac{\alpha' \beta(A'_j) + K_{i-1,j}}{\sum_{m=1}^N \alpha' \beta(A'_m) + K_{i-1,m}} = \frac{\alpha' \beta(A'_j) + K_{i-1,j}}{i - 1 + \sum_{m=1}^N \alpha' \beta(A'_m)}. \quad (16)$$

Substituting $M = N$, $o_j = \alpha' \beta(A'_j)$, and $w_{i,j} = K_{i,j}$ in eq. (15) gives eq. (16), thus completing the proof.

260 Frigyik et al. (2010, section 2) prove that the proportion of different colored balls in a *Pólya urn model* converges to the Dirichlet distribution as the number of draws approaches infinity, based on the *Martingale Convergence Theorem* (Durrett, 1999). We therefore have an approximation for the relative prestige each role-model has when evaluated by copiers. Thus, choosing the role-models for all copiers is equivalent to drawing from a Multinomial distribution where the parameters are the modified weights from a Dirichlet distribution and we have the following corollary.

266 **Corollary 3.** *The number of copiers of each role-model follows a Dirichlet-Multinomial distribution, $\mathbf{K}_i \sim \text{DM}(N, \mathbf{G}_1)$, under the conditions of Result 2.*

268 **Numerical validation.** To validate our analytical result (Corollary 3) and test its sensitivity to the assumptions ($e_i = e$ and $\alpha_i = \alpha$ for $i = 1, \dots, N$) we compare it to results of stochastic simulations of the full model. First, we computed an observed distribution of the number of copiers from the average empirical distribution of multiple simulations. We then compared this observed distribution with the expected theoretical DM distribution as can be seen in Figure 2 (a). The difference in distributions was not perceived when plotting both distributions on the same figure, so we used the difference instead. The maximum difference is 0.5 role-models, which indicate a very good fit. In addition, we tested the likelihood of the observed data to be drawn from the DM distribution, against a shuffle of the parameters vector of the DM distribution itself, as seen in Figure 2 (b). We see that the negative

log likelihood of the observed data is much higher than any other shuffled version of the parameters
 278 vector, supporting our approximation more.

Figure 2: Numerical validation of the DM approximation. We performed computational "experiments" of the role-model choice process and compared them to the DM distribution. **(A)** The difference between the DM distribution (orange) and the empirical distribution of the experiments (blue) is very small. **(B)** The log-likelihood of the DM distribution for results of the experiments (red vertical line) is much higher compared to the log-likelihood of permutations of experiments (blue histogram). Here, population size, $N = 100$; number of experiments, $m = 100$; phenotype values, $\hat{A} = 1$, $A \sim N(0, 1)$; success-bias weight, $\alpha = 0.5$. No estimation error or bias is applied, and traits are estimated and copied perfectly.

Next, we examined the fixation probability and fixation time of a favored phenotype \hat{A} when invading
 280 a population of phenotype A and compared results from the full model and the DM approximation.
 Thus, we assume the population has a single individual with phenotype \hat{A} and $N - 1$ individuals with
 282 phenotype A . We find that the number of simulations needed to sufficiently approximate our model
 with the DM approximation is roughly 1,000 (Figure 3). We examined the robustness of the DM
 284 approximation to relaxing the approximation assumptions. First, we relaxed our assumption of no
 estimation error e . Estimation error in the original model was drawn from a normal distribution, and
 286 added to the trait value before evaluation of the bias ($A_{ij} = A_j + e_i$). When estimation error is applied,
 we sample J_i for each copier i from a normal distribution with varying scale (variance). Even when the
 288 standard deviation is 0.1, the fixation probability and time is similar (Figure 4). We also relaxed our
 assumption of a uniform bias weight α (i.e., $\alpha_i = \alpha$). We allowed α to vary in the population, drawing
 290 α_j for each role-model j from a normal distribution such that $\alpha_j \sim N(0.5, q)$ where $q \in [10^{-7}, 10^{-1}]$.
 We found again that results of the DM approximation are similar to those from stochastic simulations
 292 of the full model (Figure 5).

Fixation probability and time

294 After finding that the DM distribution is a good approximation of the (within-generation) role-model
 choice process, we turn our attention to the (between-generation) evolutionary dynamics. We focus on
 296 the fixation probability and conditional fixation time (conditioned on the population reaching fixation)
 of a favored phenotype, using a diffusion-equation approximation approach, similar to analyses of
 298 population-genetic models (Kimura, 1962; Kimura and Ohta, 1969; Otto and Whitlock, 2006). We are

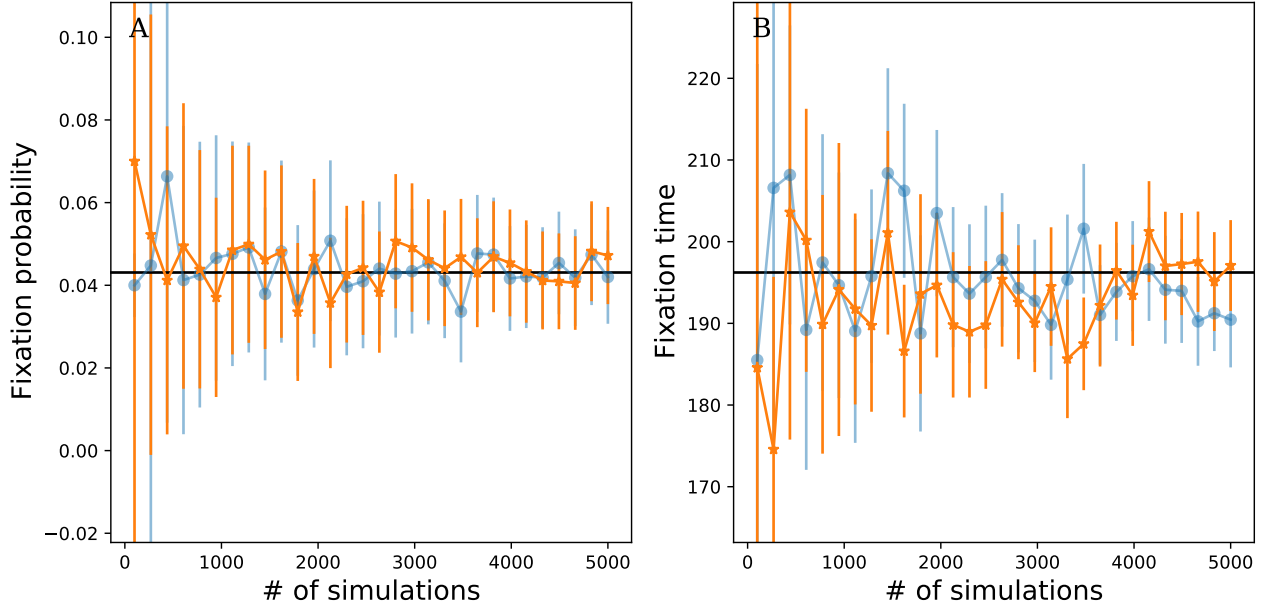

Figure 3: DM Approximation precision as function of number of simulations. Our DM approximation (orange) agrees with stochastic simulation results (blue) when using 1,000 or more simulations. Both fluctuate around the analytic fixation probability approximation (black; eq. (19)). Markers are averages across simulations, error bars are 95% confidence intervals. Here, population size, $N = 1000$; success-bias weight, $\alpha = 0.5$; phenotype values, $\hat{A} = 1$, $A = 0.7$; success-bias value, $\beta(A) = 0.956$.

mainly interested in the effect of the bias weight, α , which determines the relative effect of success and
 300 influence on prestige bias, given by eq. (10). For simplicity, we do not include role-model estimation
 error in this analysis, i.e $e_i = 0$ for every copier i . As shown above, transmission in our model is
 302 approximately DM distributed (Corollary 3 and eq. (16)).

We start by finding the expectation and variance of the change in frequency from one generation to the
 304 next, which are the drift and diffusion terms of the diffusion equation. The proof is in Appendix B.

Result 3 (Drift and diffusion terms in a constant environment). *Let x and x' be the frequency of type \hat{A}
 in a population with N individuals in the current and next generation, and β is the success coefficient
 308 of phenotype A , $\beta = \beta(A) < \beta(\hat{A}) = 1$. Then,*

$$E[x' - x] \approx x(1 - x)(1 - \beta), \quad V[x' - x] \approx x(1 - x) \left(\frac{1}{\alpha N + (1 - \alpha)} \right). \quad (17)$$

This analysis gives a surprising result relating the parameters α and β to parameters of the classical
 310 Wright-Fisher model from population genetics: the selection coefficient s , a measure of the effect of
 312 natural selection on the change in frequency of genotypes, and the effective population size, N_e , a
 measure of the effect of random genetic drift on the change in frequency of genotypes. In a diffusion-
 314 equation approximation of the classical Wright-Fisher model, the expectation and variance of the
 change in frequency are $E[x' - x] = x + x(1 - x)s + o(s)$ and $V[x' - x] = x(1 - x)/N_e$ (Kimura, 1962,

Figure 4: Robustness of DM approximations to success estimation error. Both the DM approximation (orange) and our approximation (black) agree with the stochastic simulations (blue), even with a high estimation error. Markers are averages across simulations, error bars are 95% confidence intervals. 5,000 simulations per data point; population size, $N = 1000$; success-bias weight, $\alpha = 0.1$; phenotype values, $\hat{A} = 1, A = 0.7$; bias strength parameter $J \sim N(1, \eta^2)$ where $\eta \in [10^{-7}, 10^{-1}]$.

Figure 5: Robustness of DM approximations to variation in the bias weight α . Both the DM approximation (orange) and Kimura's equation (black line) fit the stochastic simulations (blue) well even with a high variation in success bias weight. Markers for average across 5,000 simulations, error bars are 95% confidence intervals. Here, population size, $N = 1000$; success bias weight normally distributed, $\alpha \sim N(0.5, x^2)$; phenotype values $\hat{A} = 1, A = 0.7$; success bias value, $\beta(A) = 0.956$.

316 eq. 7). Therefore, we have the following result.

318 **Result 4** (Effective selection coefficient and population size). *The effective selection coefficient s and*
effective population size N_e can be written in terms of the success coefficient β (eq. (5)), the bias
 320 *weight α (eq. (10)), and the population size N as*

$$s = 1 - \beta(A), \quad N_e = \alpha N + (1 - \alpha) . \quad (18)$$

322 Note that when $N \gg 1$, $N_e \approx \alpha N$, resulting in a very convenient expression.

324 Using our effective selection coefficient, $1 - \beta$, and effective population size, N_e , with the population-
 genetics fixation probability approximation given by Kimura (1962, eq. 8), we get the following
 326 result:

Result 5 (Fixation probability). *The fixation probability is approximately*

$$328 \quad \pi(x) = \frac{1 - e^{-2(1-\beta)N_e x}}{1 - e^{-2(1-\beta)N_e}} \quad (19)$$

where x is the initial frequency of the favored phenotype \hat{A} .

330 Similarly, we can use $1 - \beta$ and N_e in the population-genetics fixation time approximation given by
 Kimura and Ohta (1969, eq. 17).

332

Result 6 (Fixation time). *The fixation time (conditioned on fixation) from an initial frequency x is*
 334 *approximately*

$$T(x) = J_1(x) + \frac{1 - \pi(x)}{\pi(x)} \cdot J_2(x), \quad (20)$$

336 where $N_e = \alpha N + (1 - \alpha)$, $S = N_e(1 - \beta)$, and

$$\begin{aligned} J_1(x) &= \frac{2}{(1 - \beta)(1 - e^{-2S})} \int_x^1 \frac{(e^{2S\xi} - 1)(e^{-2S\xi} - e^{-2S})}{\xi(1 - \xi)} d\xi , \\ J_2(x) &= \frac{2}{(1 - \beta)(1 - e^{-2S})} \int_0^x \frac{(e^{2S\xi} - 1)(1 - e^{-2S\xi})}{\xi(1 - \xi)} d\xi . \end{aligned} \quad (21)$$

338 Note that these integrals cannot be solved in closed form, so we can only estimate them numeri-
 cally.

340 **Numerical validation.** We compare our approximations (eqs. (19) and (20)) with results of sim-
 ulations of our dichotomous model using various α and β values, as well as simulations of the
 342 Wright-Fisher model, using the effective selection coefficient, $1 - \beta$, and effective population size,
 $N_e = \alpha N + (1 - \alpha)$. We find see that the two models have similar dynamics, and both are well
 344 approximated our approximations (Figure 6).

Figure 6: Fixation probability and time in a constant environment. Fixation probability and time (in generations) as a function of the success-bias weight α (bottom x-axis), or effective population size N_e (top x-axis) in the top row, and as a function of the success coefficient, $1 - \beta$, on the bottom row. The approximation (black; eq. (19)) agrees with both DM simulations (green) and Wright-Fisher simulation (orange). Fixation probability (A) is bounded by $2(1 - \beta)$ (blue). Markers are averages of 10,000 simulations, error bars show 95% confidence intervals for panels A and B and 75% for panels C and D. Here, Population size, $N = 1,000$; phenotype values, $\hat{A} = 1$, $A = 0.7$ (A and B), $A = a \cdot \hat{A}$ with $0.01 \leq a \leq 0.99$ (panels C and D); success coefficient, $1 - \beta = s = 0.044$ (A and B); success-bias weight, $\alpha = 0.01$ (panels C and D).

Changing environment . After finding a good approximation in constant environment, where the favorable trait is always \hat{A} , we proceeded to find an approximation for a changing environment. Following Ram et al. (2018), we denote k as the number of generations in which the invading phenotype is favored by success bias, and l as the number of generations in which the resident phenotype is favored by success bias. We then proceed to find expressions for the expectation and variance of the change in frequency between $n = k + l$ generations. The proof is in Appendix C.

Result 7 (Drift and diffusion terms in a changing environment). *Let x be the initial frequency of the invading phenotype and X_t is the number of individuals with the phenotype after n generation. Then,*

$$E[X_n/N - x] \simeq x(1 - x)S_n/N_e, \quad \text{and} \quad V(X_n/N - x) \simeq nx(1 - x)/N_e, \quad (22)$$

where $S_n = \sum_{t=1}^n N(1 - \beta_t)$.

Note that here, we have the average selection coefficient during a cycle of n generations as the selection coefficient eq. (19). Using the drift and diffusion terms and following Ram et al. (2018), we can approximate the fixation probability in a changing environment using

$$\tilde{\pi}(x) = \frac{1 - e^{-2\frac{S_n}{n}N_e x}}{1 - e^{-2\frac{S_n}{n}N_e}}. \quad (23)$$

Numerical validation. Comparing our approximation (eq. (23)) to simulations, we find that the approximation fits simulation results well for variable bias weights, α , which corresponds to the effective population size (Figure 7A).

However, the approximation is more sensitive to the value of the success bias coefficient β (Figure 7B). We suspect that when β is too small, there will not be many cycles in the simulations, because either the population reaches a high frequency of the fitter phenotype after just a few cycles, or the fitter phenotype becomes extinct very quickly. For such β values (below 0.65), the fixation probability exceeds even the constant environment approximation (which is the upper limit). We note that the diffusion-equation approximation assumes weak selection, or in our case, weak success bias.

We found that for a large k/l ratio (with a constant cycle length, $n = k + l = 100$), the changing environment approximation (eq. (23)) converges to the constant environment approximation (eq. (19)), see Figure 7C and Figure 7D.

The approximation follows the trend of the simulation results for all α values. When increasing the success coefficient to more than 0.15, the simulation results were located above the changing environment approximation, and below the constant environment approximation. We believe the reason is the structure of the cycle. Our proof and approximation in the changing environment are for a large amount of cycles, and when the success coefficient is too high, there might be very few cycles. Either the ideal trait is copied by enough copiers so that the influence is sufficient to negate the success bias when the cycle changes (and the trait favored by the bias becomes the disfavored), or the opposite happens, and the ideal trait gets extinct before there were enough copiers that copied it. We then tried to change the ratio between the number of cycles where \hat{A} is favored and disfavored. We showed that the approximation fits well regardless of the ratio, but when the ratio of favored generations to disfavored ones is very high, it is very similar to a constant environment model.

Figure 7: Fixation probability in a changing environment. (A) Fixation probability decreases with the the success-bias weight (bottom x-axis) and effective population size (top x-axis). The approximation (blue; eq. (23)) agrees with simulation results (orange). (B) Fixation probability increases with the success coefficient, β . When success bias is large ($1 - \beta > 0.1$), simulation results (orange) are underestimated by the changing environment approximation (blue; eq. (23)). With even larger success bias ($1 - \beta > 0.35$), even the constant environment approximation (green; eq. (19)) slightly underestimates simulation results, likely because the diffusion equation approximation assumes weak "selection". (C,D) The approximation (blue) is robust to changes in environmental cycle length, as it agrees with simulations (orange) for different sizes of the changing environment cycle, where k and l are the number of generations each trait value is under success bias. When $k > l$, the approximation and the simulations are both very close to the constant environment approximation (green), because the more generations the rare phenotype is favored, the more similar it is to the constant environment model, where it is always favored by the success bias. Markers show average of 10,000 simulations, error bars show 75% (A, C, and D) and 95% (B) confidence intervals. Here, population size, $N = 1,000$; phenotype values, $\hat{A} = 1$, $A = 0.9$ (A and B), $A = 0.8$ (C and D); In (A), the success coefficient is: $1 - \beta = s = 0.005$; In (B, C, and D) the success-bias weight is $\alpha = 0.1$.

Adaptive success-bias weight

384 We ran simulations of the role-model choice process during a single generation in which every copier evaluates its own optimal success-bias weight, α^* , which minimizes the expected squared error

386 between the estimated and the ideal trait values,

$$\alpha^* = \operatorname{argmin} \sum_{j=1}^N \frac{\alpha A_j + (1 - \alpha) K_j}{\sum_{l=1}^N \alpha A_l + (1 - \alpha) K_l} (\hat{A} - A_j)^2, \quad (24)$$

388 where A_j is the trait of role-model j and K_j the number of copiers that already chose role-model j .

390 We find that when copiers adapt their success-bias weight, it decreases with the number of copiers
 392 that have already chosen a role-model (Figure 8). Moreover, their estimation error is much lower
 compared to a constant success-bias weight, which gives roughly the same high estimation error to all
 394 copiers (compare Figure 8B and C): in this example, the adaptive weight estimation error converges
 to 0.046, whereas a constant weight gives values > 0.74 .

Figure 8: Advantage of an adaptive success-bias weight. Both success-bias weight α (A) and estimation error (B) decrease during the role-model choosing process, demonstrating that influence becomes more favored as more copiers have made their choice. However, when α is homogeneous (C), the mean estimation error doesn't decrease, regardless of α or η . The mean estimation error in the homogeneous α model is larger by a factor of 10 than the adaptive α model. Here, population size $N = 200$; estimation error is normally distributed $e \sim N(0, \eta^2)$ with standard deviation $\eta = 0.0001$ (blue), 0.001 (orange), 0.01 (green), plots are average of 300 simulations.

Discussion

During cultural transmission, cultural traits such as attitudes, values, beliefs, and behavioral patterns are transmitted between individuals, for example via copying and social learning. Some cultural traits or cultural role-models may be copied more often due to transmission biases. A common bias is success bias, in which copiers are more likely to copy a successful role-model. Many models assume that success can be accurately estimated. However, it has been suggested that because it is hard to estimate success, a more common bias is *prestige bias*—a bias towards role-models perceived to be successful in other traits (Henrich and Broesch, 2011). This perceived success can be by a manifestation of another trait, i.e indirect success, which we refer to as success in this research. Prestige can also be identified as the influence an individual has on others.

Inspired by a model by Boyd and Richerson (1988), we developed a cultural-evolution model with prestige bias that includes both indirect success and influence biases, where the latter is a bias towards role-models with many copiers. This is accomplished by a role-model choice process: each copier, in its turn, chooses a role-model, and that choice is affected both by the estimated success of each potential role-model and the number of copiers that already chose each role-mode (eq. 10).

This resulted in a model with two "nested" stochastic processes: the role-model choice process within each generation, and the cultural-evolutionary process between generations. To simplify the mathematical and computational analysis, we developed analytic approximations for the role-model choice process using the *generalized binomial distribution* (GBD, Result 1) and the *Dirichlet-Multinomial distribution* (DM, Corollary 3). The latter is especially useful, as it approximates the entire role-model choice process and only requires us to assume that the relative effect of success and influence is a characteristic of the role-model, rather than the copier.

Analyzing the model with the DM distribution, we found approximations for the fixation probability and fixation time of a cultural trait under biased transmission in a constant environment. Our approximations are similar to Kimura's evolutionary-genetic approximations, such that (i) the difference between the resident and invading cultural trait values, $1 - \beta(A)$, is equivalent to the selection coefficient in favor of a beneficial allele, s , and (ii) increasing the relative weight of influence versus success bias, α , decreases the effective population size, N_e (Figure 6).

We also analyzed a cyclic changing environment in which the identity of the success-biased trait switches after a fixed amount of generations (Figure 7). We find that, similarly to the constant environment approximation, a change in the success-bias weight α has no negative effects on the goodness-of-fit of the approximation to simulation results. We also showed that this approximation is more sensitive to changes in the success coefficient β than the constant environment approximation, and a lower value is required to have a good fit. The ratio between the number of generation in which the rare phenotype is under positive transmission bias and the number of generations in which it is under negative bias does not affect the goodness-of-fit of the approximation.

We also examined a scenario in which copiers can adapt their success-weight bias, α , to minimize their copying error, i.e., copy trait values closer to the optimal value. We found that as the role-model choice process proceeds (that is, more copiers make their choices), both the success-bias weight (adapted by copiers) and the estimation error decrease. The latter is significantly lower compared to a population using a constant, fixed success-bias weight, regardless of the value of the constant weight (Figure 8). This suggests that the later a copier makes its choice, the more it should rely on choices of previous copiers, and the less it should rely on its own estimation. The rationale, then, is that the more information a copier has, e.g. by using others as information sources, the more informative and effective his choice can be.

Prestige in the literature. According to King and Cowlishaw (2009), there are two main approaches to group decision making in nature: leadership and consensus. Leaders would usually be high-ranking members of the group: elders, individuals with many kin relations, or individuals possessing other dominant traits. King and Cowlishaw (2009) describe benefits for the closest associates of a dominant baboon, such as protection from predators. In some species, like the females of *Eulemur fulvus rufus* (Red lemur), leaders may arise due to nutritional needs, and not due to possessing superior traits (Erhart and Overdorff, 1999). In humans, leadership also has its costs and benefits. Leaders can make decisions that would most benefit them and their closest followers, while still maintaining group cohesion. However, wrong decision making that harms the group could result in negative effects for the leader. In modern society, many humans strive for prestigious positions, as they may reap rewards greater than the risk and costs to achieve them, or due to individual personality and pressure or education from the family.

Henrich and Gil-White (2001) suggested that there are two types of leadership: prestige-based and dominance-based leadership. In the latter, social status is acquired through aggression, intimidation and violence. It is also more common than prestige in non-human animals. Their definition of prestige seems to overlap with ours. They suggest prestige is composed of estimation in the eyes of other people (similar to our success bias) and commanding position in people's minds, i.e, the number of followers other people think one has, which they define as *influence*, similar to our influence bias. Henrich and Gil-White (2001) show that prestige can evolve via natural selection as an efficient process to extract reproductive benefit from the flow of socially transmitted information. They back up their claims by creating testable predictions and using evidence from the literature and experiments of social sciences. Simply put, prestige can naturally evolve when social learning already exists to save costs of individual learning.

Furthermore, according to Boyd and Henrich (2002), the process of cultural evolution doesn't require accurate replication of cultural traits, addressed as "representation" in their paper. They base their assumption on three claims: mental representations are non-discrete, cultural transmission is highly inaccurate, and mental representations are not replicated, but rather are 'reconstructed' through an inferential process that is strongly affected by cognitive 'attractors.' They describe three different models to support their points. We see a high similarity between their model and ours. Like them, we treat the cultural trait as non-discrete (in the main model, before simplifying it to facilitate analysis).

470 We also assume error in estimation, such that copiers do not precisely replicate their role-models, but
rather reconstruct them to create a potentially different trait, which is their representation of the role-
472 model's trait. In addition, the inferential process that they describe as strongly affected by cognitive
attractors may include our definition of influence bias.

474 **Empirical evidence of prestige bias** Chudek et al. (2012) report the first direct tests in children that
suggest the existence of prestige bias, defined as the tendency to learn from individuals to whom
476 others have preferentially attended, learned, or deferred. Their definition of prestige is similar to our
influence bias. They showed that the odds of 3-4 years-old children learning from an adult role-model
478 to whom bystanders had previously preferentially attended for 10 seconds were more than twice those
of their learning from a role-models whom bystanders ignored. They also note that prestige effects are
480 domain sensitive: they found that prestigious role-models were attended more when demonstrating
artifact use, whereas role-models presenting food preferences had less attendants, suggesting that the
482 domain itself (artifact use vs. food preference) can affect the attendance, and hence the prestige of the
role-model. This lead Chudek et al. (2012) to suggest that when the trait is costly to learn individually,
484 prestige will have a stronger bias. It would be interesting to include costs in our model to try and
observe these effects and dynamics in a large population.

486 According to Henrich and Broesch (2011), evolutionary theorists propose that natural selection has
favored the emergence of psychological biases for learning from those individuals most likely to
488 possess adaptive information. Thus, they studied Fijian villages to examine if and how such biases
emerge in a small-scale society. They found that Fijian villagers are more likely to learn from role-
490 models perceived as more successful/knowledgeable, both within and across domains. Their research
thus suggests that copying from those perceived as successful, rather than actually are successful, is a
492 common phenomena. They show that the social networks representing copier–role-model relationships
are centralized, suggesting that it is consistent with the prediction that people substantially share
494 notions about who is a good cultural model, but that individuals' role-model selections are influenced
by multiple factors.

496 We can also find prestige bias in more modern domains such as western medicine. Norredam and
Album (2007) examined literature from 1950 to 2005 on the effects of prestige on medicinal practices.
498 They found that active, specialized, biomedical, and high-technological types of medicine on organs
in the upper part of the bodies of young and middle-aged people were accorded high levels of prestige,
500 whereas medicine and practices with opposite characteristics had low levels of prestige. For example,
they found that surgery counts as the most prestigious specialty, while psychiatry is the less prestigious.
502 In addition, doctors tend to rank practices that require more time to master as more prestigious, while
other procedures that are considered easier to master are less prestigious. This means that there may be
504 very important practices that are neglected due to prestige bias. They concluded that such differences
in prestige may bear consequences for actual priority setting in healthcare systems.

506 Prestige bias can help to cheaply estimate and acquire knowledge, which may facilitate survival and
reproduction. However, it is not always the case, and there could be negative repercussions to this
508 bias, such as invasion of maladaptive traits. Takahashi and Ihara (2019) mention that social learning

not only takes the form of random copying of other individuals, but also involves learners' choice of what to learn and from whom to learn. They suggest a best-of- k model where an individual samples k role-models and chooses the one he deems most "successful". They mentioned that a previous mathematical analysis has shown that it may sometimes result in maladaptive cultural evolution when the payoffs associated with cultural variants vary stochastically. In such a case, learners may be selectively disfavored and in the long run replaced by unbiased learners, who simply copy someone chosen at random. They developed new mathematical models that are simpler and mathematically tractable. They found that best-of- k learning, unlike unbiased learning, can facilitate the invasion of an on average inferior variant that sometimes gives a very high payoff. Our model, which includes influence bias, is consistent with this claim. When a maladaptive trait is "piggybacking" a role-model with high influence, this trait could spread in the population. In addition, they show that best-of- k learning can be stable against invasion by unbiased learning if social learning is sometimes combined with individual learning. Our model only includes social learning, and not individual learning, but it could be interesting to combine it with individual learning and see how it affects the dynamics.

Prestige bias can also accelerate reversal of harmful traditions such as child marriage and domestic violence. Efferson et al. (2020) suggest a *spillover* mechanism, in which an intervention affects a large enough group in a target population, so that others not included in the intervention also change their behavior. They found that there are individuals who act as *agents*, who are often looked upon, and therefore they are ideal targets for interventions. This is similar to influential role-models in our model, where a prestigious individual will be copied more often, and will therefore spread his trait faster and wider in the population. They also suggest a way to use this phenomena to change existing traditions in a population. It is very clear however, that just as it can be used to end harmful traditions, the same agents could start harmful traditions.

Dunbar (2009) hypothesized that larger, more complex brains can store and manage more information and in turn, this information can support the costs of a larger brain. Following up on this, Muthukrishna and Henrich (2016) offered that prestige can directly affect human physical evolution. They present a concept called *cultural brains*—brains that evolved primarily for the acquisition of adaptive knowledge. They then develop a model that predicts a strong relationship between brain size and group size, because group size also provides access to more adaptive knowledge. They also presented the *cumulative cultural brain* hypothesis, which proposes that human brains have evolved with an ability and tendency for selective, high-fidelity social learning. As part of this process, there are a variety of strategies and biases that have evolved to hone in on the most adaptive knowledge. These strategies and biases include direct and indirect cues of the popularity of cultural traits (e.g. success and prestige biases). They suggest that one of the reasons for the extreme increase in brain size in humans is the ability to "cheaply" acquire adaptive knowledge via transmission biases such as prestige.

Further work. One path forward is an analysis of the dynamics of the adaptive success-bias weight model, in which every copier chooses its α . It would be interesting to see if the mean estimation error and the adaptive weight, α^* , are converging to specific values, and how they are affected by the model parameters. It may also be possible to relax the assumptions required for our approximations,

548 such as homogeneous estimation error and success-bias weight. Lastly, it would be interesting to
analyze the continuous model and determine how much it differs from the dichotomous model.

550 Another way to expand our model is to account for the two types of prestige or leadership suggested
by Van Vugt and Smith (2019) that are attributed to Confucius and Machiavelli. Confucius viewed
552 leaders as role-models who exercise influence through possessing superior knowledge, skills, and
(outstanding) personal qualities. This fits the success bias in our model. In contrast, Machiavelli
554 viewed leaders as rulers who exercise influence by imposing costs through (the threat of) punishment
and violence. Van Vugt and Smith (2019) suggest that these two opposing views are both partially
556 supported by the available evidence but each one on its own offers an incomplete view of the complex
and dynamic concept of leadership. Several adjustments could be made so that our model reflects
558 these leadership styles, such as assuming there is a correlation between phenotype to leadership style.
The emerging cultural-evolutionary dynamics and their dependence on the costs and benefits are
560 intriguing.

So far we examined different variations of our model using a Wright-Fisher model as our basis, mainly
562 because we wanted to base our model on a known one from the literature, namely Boyd and Richerson
(1988) indirect bias model. When approximating our model by comparing it to a Polya Urn process,
564 we noticed that our model would be identical to a model where every copier that chose a role-model
would copy its trait and join the role-models during the selection process. Based on this, we theorize
566 that when using a Moran model as basis instead of a Wright-Fisher mode, we would get very similar,
and perhaps identical results. It would be interesting to run simulations and analyze that model, to
568 prove or disprove our hypothesis.

Conclusions. Here, we studied a model of cultural evolution under two transmission biases: the
570 commonly studied success bias, together with influence bias, which has so far received less attention.
We found approximations for this complex dynamics. We then showed that success bias affects the
572 evolutionary dynamics much like natural selection does, whereas influence bias has a similar effect to
random genetic drift. We also find a clear advantage to individuals that can choose the relative weight
574 of the two biases.

Appendices

Appendix A General binomial distribution approximation

Proving $E[K_{Nj}] = \alpha_j \cdot \beta(A_j + e) / \overline{\alpha \cdot \beta(A + e)}$, where the averaging in the denominator is over the role-models index, j .

Proof. The initial prestige of role-model j based on eq. (10) is

$$G_{1,j} = \frac{\alpha_j \cdot \beta(A_j + e)}{\sum_{m=1}^N \alpha_m \cdot \beta(A_m + e)} . \quad (A1)$$

The denominator of eq. (A1) can also be formulated as:

$$\sum_{m=1}^N \alpha_m \beta(A_m + e) = N \cdot \overline{\alpha \cdot \beta(A + e)} , \quad (A2)$$

where $\overline{\alpha \beta(A + e)}$ is the mean value of $\alpha_m \cdot \beta(A_m + e)$ for all m . Using eq. (A2) and **Corollary 1** we get,

$$E[K_{Nj}] = \alpha_j \cdot \beta(A_j + e) / \overline{\alpha \cdot \beta(A + e)} , \quad (A3)$$

Appendix B Drift and diffusion in a constant environment

Proving drift and diffusion terms in a constant environment. Let x and x' be the frequency of type \hat{A} in a population with N individuals in the current and next generation, and β is the success coefficient of phenotype A , $\beta = \beta(A) < \beta(\hat{A}) = 1$. Then,

$$E[x' - x] \approx x(1 - x)(1 - \beta) , \quad V(x' - x) \approx x(1 - x) \left(\frac{1}{\alpha N + (1 - \alpha)} \right) .$$

Proof. Let X be the number of individuals of type \hat{A} such that $x = X/N$. X' is the number of individuals with \hat{A} in the next generation. The expected number of individuals is (due to the DM approximation),

$$E[X'] = N \frac{\alpha_1}{\alpha_1 + \alpha_2} , \quad (B1)$$

where $\alpha_1 = \alpha'X$ and $\alpha_2 = \alpha'(N - X)\beta$, from eq. (11). To use frequencies instead of counts, $E[x'] = E[X'/N] = \frac{1}{N}E[X']$. Putting it together,

$$\begin{aligned} E[x'] &= \frac{1}{N}N \frac{\alpha'xN}{\alpha'xN + \alpha'N(1-x)\beta} = \frac{x}{x + (1-x)\beta} \\ &= \frac{x}{x + (1-x) - (1-x) + (1-x)\beta} = x \frac{1}{1 - (1-x)(1-\beta)} \\ &= x(1 + (1-x)(1-\beta) + o(\beta)) = x + x(1-x)(1-\beta) + o(\beta), \end{aligned} \quad (B2)$$

following Durrett (2008, p. 253, ch 7.2) and because $1/(1-y) = 1 + y + y^2 + \dots$

By definition, x is constant, so $E[x] = x$. We therefore have

$$E[x' - x] = E[x'] - E[x] = x(1-x)(1-\beta) + o(1-\beta), \quad (B3)$$

which gives us the drift term of the diffusion equation.

Using the variance of the DM distribution,

$$V(X') = N \frac{\alpha_1}{\alpha_1 + \alpha_2} \left(1 - \frac{\alpha_1}{\alpha_1 + \alpha_2}\right) \left(\frac{N + \alpha_1 + \alpha_2}{1 + \alpha_1 + \alpha_2}\right). \quad (B4)$$

Again, we want to use frequencies so we have $V(X'/N) = \frac{1}{N^2}V(X')$. Putting it together with our model notations,

$$V(x') = \frac{1}{N^2}N \frac{x}{x + (1-x)\beta} \left(1 - \frac{x}{x + (1-x)\beta}\right) \left(\frac{N + \alpha'xN + \alpha'N(1-x)\beta}{1 + \alpha'xN + \alpha'N(1-x)\beta}\right). \quad (B5)$$

Following Durrett (2008, ch 7.2), we assume $\beta \approx 1$, such that

$$\frac{x}{x + (1-x)\beta} \approx x \quad (B6)$$

and for the entire variance expression we get

$$V(x') \approx \frac{1}{N}x(1-x) \left(\frac{N + \alpha'xN + \alpha'N - \alpha'xN}{1 + \alpha'xN + \alpha'N - \alpha'xN}\right) = x(1-x) \left(\frac{1 + \alpha'}{1 + \alpha'N}\right). \quad (B7)$$

Now because x is a constant, $V(x) = 0$, and therefore

$$V(x' - x) = V(x') - V(x) \approx x(1-x) \left(\frac{1 + \alpha'}{1 + \alpha'N}\right). \quad (B8)$$

α' is the odds ratio of the bias weight,

$$\alpha' = \frac{\alpha}{1 - \alpha}. \quad (B9)$$

Combining eq. (B8) and eq. (B9) we get:

$$V(x' - x) \approx x(1 - x) \left(\frac{1 + \frac{\alpha}{1-\alpha}}{1 + \frac{\alpha}{1-\alpha}N} \right) = x(1 - x) \left(\frac{1}{\alpha N + (1 - \alpha)} \right). \quad (\text{B10})$$

This gives the diffusion term of the diffusion equation.

Appendix C Drift and diffusion in a changing environment

Proving drift and diffusion terms in a changing environment. Let x be the initial frequency of the invading phenotype and X_t is the number of individuals with the phenotype at time t . Then,

$$E[X_t/N - x] \simeq x(1 - x)S_t/N_e, \quad \text{and} \quad V(X_t/N - x) \simeq tx(1 - x)/N_e,$$

where $S_t = \sum_{i=1}^t N(1 - \beta_i)$.

Proof. Let $s_t = N(1 - \beta_t)$, and $S_n = \sum_{i=1}^n s_i$, where β_t is $\beta(A)$ at generation t . We prove by induction both terms in eq. (22). From eq. (B3) we know that

$$E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \middle| X_t \right] = \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) (1 - \beta_{t+1}) = \frac{1}{N} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) s_{t+1}. \quad (\text{C1})$$

Also note that using the definition of $V(y) = E[y^2] - (E[y])^2$

$$\begin{aligned} E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] &= E \left[\frac{X_t}{N} - \left(\frac{X_t}{N} \right)^2 \right] = E \left[\frac{X_t}{N} \right] - E \left[\left(\frac{X_t}{N} \right)^2 \right] \\ &= E \left[\frac{X_t}{N} \right] - V \left(\frac{X_t}{N} \right) - \left(E \left[\frac{X_t}{N} \right] \right)^2. \end{aligned} \quad (\text{C2})$$

We can now use the induction assumption of $V(\frac{X_t}{N})$ to get

$$E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] \simeq E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right) - \frac{1}{N_e} tx(1 - x). \quad (\text{C3})$$

From eq. (C1) we know that

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] &= \frac{1}{N} s_{t+1} E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] \simeq \frac{1}{N} s_{t+1} \left(E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right) - \frac{1}{N_e} tx(1 - x) \right) \\ &\simeq \frac{1}{N} s_{t+1} \cdot E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right) - \frac{1}{N_e N} s_{t+1} tx(1 - x). \end{aligned} \quad (\text{C4})$$

Now we omit $O(\frac{1}{N_e N})$ and get

$$E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] \simeq \frac{1}{N} s_{t+1} \cdot E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right). \quad (\text{C5})$$

We now look at the induction assumption to see that

$$E \left[\frac{X_t}{N} - x \right] = E \left[\frac{X_t}{N} \right] - E[x] = E \left[\frac{X_t}{N} \right] - x , \quad (\text{C6})$$

so using the assumption we get

$$\begin{aligned} E \left[\frac{X_t}{N} \right] &\simeq \frac{1}{N} S_t x (1-x) + x , \\ 1 - E \left[\frac{X_t}{N} \right] &\simeq 1 - \frac{1}{N} S_t x (1-x) + x . \end{aligned} \quad (\text{C7})$$

We use both expressions in eq. (C5) and get

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] &\simeq \frac{1}{N} s_{t+1} \left(\frac{1}{N} S_t x (1-x) + x \right) \left(1 - \frac{1}{N} S_t x (1-x) + x \right) \\ &\simeq \frac{1}{N} s_{t+1} \cdot x (1-x) , \end{aligned} \quad (\text{C8})$$

after again omitting $O(\frac{1}{N^2})$ terms. To conclude the proof, we note that

$$E \left[\frac{X_{t+1}}{N} - x \right] = E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] + E \left[\frac{X_t}{N} - x \right] , \quad (\text{C9})$$

so again using the induction assumption, together with eq. (C8) we get

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} - x \right] &\simeq \frac{1}{N} s_{t+1} \cdot x (1-x) + \frac{1}{N} S_t \cdot x (1-x) \\ &\simeq \frac{1}{N} x (1-x) (S_t + s_{t+1}) \simeq \frac{1}{N} S_{t+1} x (1-x) , \end{aligned} \quad (\text{C10})$$

which proves the drift term.

For the diffusion term, we use a property of variance,

$$V \left(\frac{X_{t+1}}{N} \right) = E \left[V \left(\frac{X_{t+1}}{N} \middle| X_t \right) \right] + V \left(E \left[\frac{X_{t+1}}{N} \middle| X_t \right] \right) . \quad (\text{C11})$$

Using eq. (C1) we see that

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} \middle| X_t \right] - E \left[\frac{X_t}{N} \middle| X_t \right] &= \frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \\ E \left[\frac{X_{t+1}}{N} \middle| X_t \right] &= \frac{X_t}{N} + \frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) . \end{aligned} \quad (\text{C12})$$

Using eq. (B10) we get

$$V \left(\frac{X_{t+1}}{N} \middle| X_t \right) = \frac{1}{N_e} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) , \quad (\text{C13})$$

and using the equation $y'(1 - y') \simeq y(1 - y)$ on the first part of eq. (C11) we get

$$E \left[V \left(\frac{X_{t+1}}{N} \middle| X_t \right) \right] = \frac{1}{N_e} E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] \simeq \frac{1}{N_e} x(1 - x) . \quad (\text{C14})$$

Moving on to simplify the second part of eq. (C11) using eq. (C12),

$$V \left(E \left[\frac{X_{t+1}}{N} \middle| X_t \right] \right) = V \left(\frac{X_t}{N} + \frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right) \quad (\text{C15})$$

Now, because $\frac{X_t}{N}$ is a frequency, i.e $0 \leq X_t/N \leq 1$, we know that $V \left(\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right) \leq \frac{1}{4}$. We therefore find that

$$V \left(\frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right) \leq \frac{1}{4N^2} s_{t+1}^2 ; , \quad (\text{C16})$$

and so it can be ignored. Combining our equations we get

$$V \left(E \left[\frac{X_{t+1}}{N} \middle| X_t \right] \right) = V \left(\frac{X_t}{N} \right) + O \left(\frac{1}{N^2} \right) \simeq V \left(\frac{X_t}{N} \right) . \quad (\text{C17})$$

Using the induction assumption and eq. (C14),

$$V \left(\frac{X_{t+1}}{N} \right) \simeq \frac{1}{N_e} x(1 - x) + \frac{1}{N_e} t x(1 - x) \simeq \frac{1}{N_e} x(1 - x)(t + 1) \quad (\text{C18})$$

which proves the diffusion term.
