Abstract

If the traits of more successful individuals are more likely to be adopted, the resulting cultural transmission is described as being success-biased. In contrast, if the traits of ‘prestigious’ individuals—those individuals that have already been copied many times—are more likely to be adopted, this is described as prestige-biased cultural transmission. In this case, prestige can be used as a convenient proxy for success. However, it is unclear how success and prestige biases interact to determine the outcome of cultural evolutionary dynamics. Here, we aim to clarify this using mathematical analysis and stochastic simulations. We find analytic approximations to the stochastic role-model choice process that facilitate the mathematical analysis and reduce the computational complexity of simulations. Approximations are given to the fixation probability and the fixation time of an invading cultural trait in different environments. Our results show that success bias effectively plays the role of natural selection, whereas prestige bias effectively plays the role of genetic drift. Prestige bias, which may be strong in highly social communities, also accelerates the evolutionary dynamics, as can be expected in a rich-get-richer process. These results signify a step forward in understanding how different cultural transmission biases interact.

Introduction

24 Cultural transmission of attitudes, preferences, beliefs, norms, and behaviors may combine vertical
transmission, in which parents transmit to their offspring; oblique transmission, in which adults
26 (teachers, leaders, and even strangers) transmit to unrelated offspring; and horizontal transmission, in
which individuals from the same age cohort transmit to one another [6]. It has been demonstrated that
28 non-vertical cultural transmission can maintain maladaptive traits, which can be beneficial in changing
environments [23, 56].

30 Transmission biases may cause a cultural trait to have a higher rate of transmission than its frequency in
the population. *Success bias* occurs when individuals prefer to copy from role models that demonstrate
32 success in some activity, such as fishing, growing yams, using medicinal plants [26], or hunting [55],
and it can increase the probability of learning a trait that is present in those successful individuals [54].
34 Indeed, in a tournament between learning strategies [9], most winning strategies included a mixture
of success-biased social learning and individual learning, implying that success-biased learning is a
36 good strategy, but that by itself it is not enough to best other strategies, even when success is measured
accurately. Jimenez and Mesoudi [1] also note that a way to acquire adaptive social information is by
38 preferentially copying competent individuals within a valuable domain (which they also call success
bias). However, they claim that competence within a domain is often difficult or impossible to directly
40 assess, and therefore people tend to use indirect cues of success. Henrich and Broesch [26] have also
suggested that direct assessment of success may be “noisy, unreliable or unavailable” and therefore
42 copiers should also take into account indirect measures of perceived success (e.g., “great fishermen
may be chosen as role-models for growing yams”).

44 Boyd and Richerson [7, Ch. 5] suggested that the assessment of success can be divided to three
categories: *direct bias*, *indirect bias* and *frequency-dependent bias*. Direct bias occurs when one
46 phenotype is more attractive than other phenotypes, and is evaluated by *directly* testing the trait. For
example, an individual observing a ping-pong match can try the observed paddle grips to determine
48 which grip is better. Frequency-dependent bias occurs when the probability of copying a phenotype is
higher or lower than the frequency of the phenotype among demonstrators. For example, suppose the
50 common paddle grip is used by 60% of the demonstrators; if the this grip is adopted by 80% of copiers,
then transmission is under positive frequency bias, also called *conformity*; if it is adopted by 40% of
52 copiers, then transmission is under negative frequency bias, or *anti-conformity* [17]. The effects of
conformity and anti-conformity on cultural evolution have been studied with both models [37, 38, 39]
54 and experiments [5]. Indirect bias occurs when a copier uses some observed phenotype to evaluate
the attractiveness of a potential role-model. For example, an observer may copy the paddle grip of
56 the ping-pong player who scored more points in the match, thus indirectly evaluating the grip by the
points scored. However, this may cause mismatches between the copied trait and the rest of the cultural
58 or genetic repertoire of the individual [53]. Furthermore, Boyd and Richerson [7, Ch. 8] suggest
that maladaptive traits may spread widely in a population if indirect bias is strong enough, e.g., by a

runaway process caused by a cultural equivalent of sexual selection [10]. Indeed, helping behaviors can evolve due to horizontal transmission bias even without any benefit to the recipient [36].

Henrich and Gil-White [28] noted that “the most skilled/knowledgeable role-models will, on average, end up with the biggest and most lavish clienteles, so the size and lavishness of a given model’s clientele size (the *prestige*) provides a convenient and reliable proxy for that person’s information quality”. Thus, they predicted that skilled individuals have higher status, that people preferentially copy high-status individuals, and therefore that prestigious individuals may be influential even beyond their domain of expertise. They defined prestige as “freely conferred deference”, in contrast to *dominance*, and provided examples from the anthropological literature [28]. Similarly, the New Oxford American Dictionary defines prestige as the “widespread respect and admiration felt for someone or something on the basis of a *perception* of their achievements or quality.”. Chudek et al. [32] have also defined prestige bias as “a tendency to learn from individuals to whom others have preferentially attended, learned or deferred” and demonstrated its occurrence in 3-4 year old children. Nakata et al. [63] define such a bias as a “prestige bias based on second-order cues,” in which “Social learners can use the extent of attention and the amount copied from others as cues for prestige.” Henrich and Broesch [26] have further suggested that prestige bias can, over generations, lead to cultural adaptations and that although prestige can lead to maladaptive traits spreading in the population, it can also accelerate the spread of adaptive traits.

The distinction between success and prestige bias is important, as prestige is a context-dependent bias, rather than a content-dependent bias: it does not depend on the phenotype itself but rather on the number of copiers that have already copied each role-model, which may be easier and more accurate to estimate than success. Prestige bias is also frequency independent (see Corollary 1 below), and thus it differs from conformity [37, 38, 39], which depends on the frequency of a trait in the population or in a sample of role-models, rather than the social dynamics of copying.

Prestige bias may be more common in humans than success bias [8]. In contemporary human society, social media make it especially easy to estimate the social and cultural influence individuals have over others, which can have an effect on decision making. Online social networks such as *Facebook* and *Instagram* are known to affect the influence of individuals [41, 42, 43], and specific marketing practices have been invented to capitalize on this effect [40]. However, despite many mentions of prestige in the cultural evolution literature, there are few models of prestige bias.

Here, we develop a stochastic model of cultural transmission with both indirect success bias and prestige bias to examine their relationship in contribution to the cultural evolution of populations. We find analytic approximations for this model. We also find approximations for the probability and time to fixation of a ‘successful’ phenotype (i.e., that is subject to success bias) in both a constant and a periodically changing environment. Comparing these approximations to Kimura’s approximations for the fixation of a favorable allele [21, 47], we demonstrate that success and prestige bias play the role of natural selection and genetic drift, respectively.

Models

98 We begin with a continuous-trait model with indirect success bias, previously suggested by Boyd and
Richerson [7]. Note that the indirect success bias is due to an indirect evaluation, in which a certain
100 phenotype is used to evaluate the success of potential role-models. We extend this model to include
prestige bias, which introduces a within-generation model-choice process. To facilitate mathematical
102 analysis, we also develop a simpler version of the model with a dichotomous trait.

We implement our stochastic models and approximations, perform statistical analyses, and pro-
104 duce figures using Python [44] with NumPy [45] and Matplotlib [46]. Source code is available at
<https://github.com/yoavram-lab/PrestigeBias>.

106 Continuous trait

We follow the Boyd and Richerson model [7], assuming only oblique transmission of a single trait. This
108 focus on oblique transmission (copying from non-parental adults) and, therefore, fitness differences
between trait values are neglected since there is no correlation between the traits of parents and
110 offspring. We consider a population of N individuals, described by a single trait that takes continuous
values. At each generation, N naive individuals, or copiers, each choose a single role-model from the
112 entire previous generation. Each copier then copies its trait value from the chosen role-model. Note
that our transmission models are slightly different from those modeled before, e.g. [7, 38, 58], in
114 which the population is infinite and each copier samples n role-models and then copies its trait from
one or more of the sampled role-models.

116 Similar to a Wright-Fisher model, generations are non-overlapping, and the entire population is
replaced in each generation. The population at time t can be described by $\mathbf{A}(t) = (A_1(t), \dots, A_N(t))$
118 where $A_i(t)$ is the trait value of individual i at time t , and the initial population is drawn from a
standard normal distribution, $\mathbf{A}(0) \sim N(0, 1)$. Cultural transmission is modeled by a function F such
120 that

$$A_i(t+1) = F_i(\mathbf{A}(t)) . \quad (1)$$

122 **Success bias.** Boyd and Richerson [7, Ch. 8, p. 247-249] describe a transmission algorithm by defining
 F , a weighted average of the traits of all role-models, as

$$124 \quad F_i(\mathbf{A}) = \sum_{j=1}^N G_{i,j} \cdot A_{i,j} , \quad (2)$$

where $G_{i,j}$ is the success bias of role-model j in the eyes of copier i ,

$$126 \quad G_{i,j} = \frac{\beta(A_{i,j})}{\sum_{k=1}^N \beta(A_{i,k})} , \quad (3)$$

128 $A_{i,j}$ is the absolute trait value that copier i estimates for role-model j with some error $e_i \sim N(0, \eta^2)$,

$$A_{i,j} = A_j + e_i, \quad (4)$$

130 and $\beta(\cdot)$ is the bias function that quantifies the success bias of a role-model [7, eq. 5.11],

$$\beta(A_{i,j}) = b \cdot \exp\left(-\frac{(A_{i,j} - \hat{A})^2}{2J}\right), \quad (5)$$

132 with \hat{A} as the arbitrary optimal trait value, and J and b as parameters that control the bias strength; unless otherwise mentioned, we set $b = J = 1$. Therefore, $G_{i,j}$ is a relative success score that copier i assigns to role-model j .

Boyd and Richerson [7] note that the deterministic blended transmission algorithm they use has 136 alternatives. We develop a similar stochastic model with transmission from a single random role-model where instead of eq. (2) we define the transmission function F as a random variable with its 138 distribution given by

$$\Pr(F_i(\mathbf{A}) = A_j) = G_{i,j}; \quad (6)$$

140 here $G_{i,j}$ is the probability that copier i chooses to copy the trait of role-model j .

Prestige bias. We introduce a new element to the model by assuming that in each generation copiers 142 choose their role-models one by one so that the choice of one copier can affect the choice of other copiers. We formulate this assumption in the following. Denote by $K_{i,j}$ the number of copiers that 144 choose role-model j after copier i chose a role-model. Thus, i out of N copiers had already chosen a role-model, $\sum_{j=1}^N K_{i,j} = i$, and there are $N - i$ copiers that have yet to choose a role-model. The 146 stochastic process of role-model choice,

$$\{\mathbf{K}_i = (K_{i,1}, \dots, K_{i,N})\}_{i=1}^N, \quad (7)$$

148 is described by the recurrence equation

$$K_{i,j} = K_{i-1,j} + S_{i,j}, \quad i, j = 1, 2, \dots, N, \quad (8)$$

150 where $S_{i,j} = 1$ if the i -th copier chose role-model j and 0 otherwise, and the initial state is $K_{0,j} = 0$.

152 Following eq. (6), the probability that the i -th copier chose role-model j is given by the *influence* of role-model j in the eyes of copier i ,

$$154 \quad \Pr(S_{i,j} = 1 \mid S_{1,j}, S_{2,j}, \dots, S_{i-1,j}) = G_{i,j}. \quad (9)$$

The influence $G_{i,j}$ of role-model j in the eyes of copier i is determined by success—the estimated 156 biased trait value $\beta(A_{i,j})$ —and prestige—the number of copiers that chose role-model j before copier i ,

$K_{i-1,j}$, replacing eq. (3) with

$$G_{i,j} = \frac{\alpha_{ij} \cdot \beta(A_{i,j}) + (1 - \alpha_{ij}) \cdot K_{i-1,j}}{W_i}, \quad (10)$$

where W_i is a normalizing factor that sums the numerator over all role-models ($1 \leq j \leq N$) to ensure $\sum_{j=1}^N G_{i,j} = 1$. Here, the success-bias weight $\alpha_{i,j}$ determines the relative weighting of success and prestige bias. It is a characteristic of the interaction of role-model j with copier i that determines the relative significance of success vs. prestige bias in the role-model's overall influence in the eyes of the copier. Different individuals may evaluate the importance of success and prestige differently. Additionally, we assume each role-model displays its prestige and success individually. For example, individuals with more followers but lacking skill may emphasize the number of their followers rather than their skill (i.e., have lower $\alpha_{i,j}$ value). Finally, the trait of role-model j estimated by copier i , $A_{i,j}$, remains as in eq. (4).

168 Dichotomous trait

We introduce a simplified version of the above model where the trait has only two phenotypes: an optimal phenotype \hat{A} and a sub-optimal phenotype A . All role-models with the same phenotype will contribute to the probability that that phenotype is transmitted and thus prestige is determined by the number of copiers that have already chosen a role-model with either phenotype. In addition, for simplicity and for easier mathematical analysis, we assume α is homogeneous and constant ($\alpha_{i,j} = \alpha$), which entails exchangeability between role-models. Therefore, the probability that the i -th copier copies phenotype A is

$$G_{i,A} = \frac{\alpha \cdot (N - X)\beta(A) + (1 - \alpha) \cdot K_{i-1,A}}{\alpha \cdot (N - X)\beta(A) + \alpha \cdot X + (1 - \alpha) \cdot (i - 1)}, \quad (11)$$

where X is the number of role-models with trait \hat{A} and $K_{i-1,A}$ is the number of copiers that already chose A when copier i chooses a role-model, and assuming that $\beta(\hat{A}) = 1$ (thus the term αX in the denominator). Complementing this, the probability of the i -th copier to copy phenotype \hat{A} is $G_{i,\hat{A}} = 1 - G_{i,A}$. Figure S1 shows some examples of model dynamics for various values of α .

Results

Our models are defined by two nested stochastic processes. Change over multiple generations is described by the dynamics of the phenotype distribution at each generation, $\{\mathbf{A}(t)\}_t$, see eq. (1). The transition from one generation to the next is described by the number of copiers each role-model has after i copiers have chosen a role-model, $\{\mathbf{K}_i\}_{i=1}^N$, see eq. (7). We emphasize that the models are nested: $\mathbf{A}(t + 1)$ can be computed from $\mathbf{A}(t)$ by evaluating \mathbf{K}_N , where $K_{N,j}$ is the number of copiers that chose role-model j after all copiers chose a role model. However, the former requires iterating over eqs. (8) and (9). Thus, we sought to find an equivalent stochastic process that has the same joint distribution as \mathbf{K}_N . We found two approximations for the distribution of \mathbf{K}_N , summarized here and explained in detail below. In both approximations we assume that the success-bias weight is either

completely homogeneous, $\alpha_{i,j} = \alpha$, or that $\alpha_{i,j} = \alpha_j$ is a characteristic of role-model j that does not vary between copiers. Note that these approximations apply for both the and the continuous trait (eq. (10)) and the dichotomous trait (eq. (11)) models.

Generalized binomial distribution approximation. The number of copiers of a specific role-model at each step, $K_{i,j}$, follows the *generalized binomial distribution* [18] and therefore, (i) the expected number of copiers of role-model j equals its influence in the eyes of the first copier, multiplied by the total number of copiers, that is, $E[K_{N,j}] = N \cdot G_{1,j}$ if trait estimation error is uniform for all copiers ($e = e_i$ for $i = 1, \dots, N$); and (ii) the expected number of copiers of each role-model equals its relative biased trait value, similar to the role of relative fitness in population-genetic models, that is, $E[K_{N,j}] = \beta(A_j + e)/\bar{\beta}$ if the bias weight is uniform for all role-models ($\alpha = \alpha_j$ for $j = 1, \dots, N$), where $\bar{\beta} = 1/N \sum_{j=1}^N \beta(A_j + e)$ is the population mean estimated trait value.

Dirichlet-Multinomial distribution approximation. The role-model choice process, $\{\mathbf{K}_i\}_{i=1}^N$, is equivalent to a *Pólya urn* model if trait estimation error is uniform for all copiers ($e = e_i$ for all $i = 1, \dots, N$). Hence, the number of copiers of each role-model \mathbf{K}_N at the end of the role-model choice process follows the Dirichlet-Multinomial distribution.

After finding these approximations for the role-model choice process, we focus on the dichotomous-trait model, in which mathematical analysis is simpler, and studied the fixation probability and time in both a constant and a changing environment.

Generalized binomial distribution (GBD) approximation

The generalized binomial distribution (GBD) emerges from a series of dependent Bernoulli trials (in contrast to the standard binomial distribution in which trials are independent) and is denoted by $GBD(n, p, \theta)$ where n is the number of trials, p is the probability of success of the first trial, and θ is the correlation between trials (the latter can be estimated from data, but its value is insignificant for our approximation). Note that $\theta = 0$ gives the standard binomial distribution.

Result 1 (Generalized binomial distribution approximation). *The number of copiers of role-model j after i copiers have chosen a role-model follows the generalized binomial distribution,*

$$K_{i,j} \sim \text{GenBin}(i, \alpha_j \cdot \beta(A_j + e), \theta)$$

if $e_i = e$ for all copiers $i = 1, \dots, N$; the success-bias weight only depends on the role-model and not the copier, i.e., $\alpha_{i,j} = \alpha_j$ for all $i = 1, \dots, N$; and θ is the correlation between successive role-model choices.

Proof. Let $Q_j(k, i) = P(K_{i,j} = k \mid K_{i-1,j})$ be the probability that exactly k out of i copiers choose role-model j given $K_{i-1,j}$ out of $i - 1$ copiers chose role-model j . Using conditional probability and eq. (8),

$$Q_j(k, i) = P_j(S_{i,j} = 1 \mid k - 1, i - 1) \cdot Q_j(k - 1, i - 1) + P_j(S_{i,j} = 0 \mid k, i - 1) \cdot Q_j(k, i - 1), \quad (12)$$

where $S_{i,j} = 1$ when the i -th copier chooses role-model j . Equation (12) is equivalent to eq. (2.1) in [18], which completes the proof.

This result gives the following corollary on the expected number of followers of a given role-model j by the end of the role-model choice process, $K_{N,j}$.

Corollary 1. *The expected number of copiers of role-model j after all copiers have chosen a role-model is $E[K_{N,j}] = N \cdot G_{1,j}$, where $G_{1,j}$ is the probability of the first copier to copy role-model j . In addition, $E[K_{N,j}] = \alpha_j \cdot \beta(A_j + e) / \overline{\alpha \cdot \beta(A + e)}$, where the averaging in the denominator is over the role-models index, j .*

Proof. The expected value of the GBD is $E[K_{N,j}] = N \cdot Q_j(1, 1)$, see Drezner and Farnum [18, eq. (2.3)]. Here, $Q_j(1, 1)$ is the initial probability to choose role-model j , before any role-model choices are made, such that $Q_j(1, 1) = G_{1,j}$ by definition. The rest of the proof is in Appendix A.

Note that $G_{1,j} = \alpha_{1,j} \beta(A_{1,j}) / \sum_{i=1}^N \alpha_{i,j} \beta(A_{i,j})$ (see eq. (10) with $K_{0,j} = 0$). In the limit of $\alpha_{i,j} \rightarrow 0$, that is with only prestige bias, we get $G_{1,j} = 1/N$, and from Corollary 1, the expected number of copiers of role-model j is 1. Therefore, prestige bias is frequency independent, in contrast to conformity bias.

The special case where the bias weight is uniform for all role-models ($\alpha = \alpha_j$ for $j = 1, \dots, N$) is interesting, because we can evaluate the expected number of copiers using a linear equation

$$E[K_{N,j}] = N \cdot \frac{\alpha \cdot \beta(A_j + e)}{\sum_{m=1}^N \alpha \cdot \beta(A_m + e)} = \beta(A_j + e) \left/ \overline{\beta(A + e)} \right., \quad (13)$$

where the only variable is $A_j + e$, because $\overline{\beta(A + e)}$ is the mean of the distribution of the trait values, modified by some constant parameters of β . We can then write $L = 1/\overline{\beta(A + e)}$ and

$$E[K_{N,j}] = L \cdot \beta(A_j + e). \quad (14)$$

Numerical validation. To validate that the GBD approximation for the number of copiers of a role-model is correct (eq. (13)), we ran 1,000 simulations of the full model, and compared the results with Corollary 1. We compare the distribution of the number of copiers by plotting the histograms of both our simulation results and the expected values based on Corollary 1.

Although basic, Figure S2 shows a good fit of the GBD approximation. We perform more extensive validations on the Dirichlet-Multinomial approximation (see below), because that is what we will use in our analysis.

252 Dirichlet-Multinomial distribution (DMD) approximation

Pólya urn model. This stochastic process consists of N draws from an urn with an initial number of
 254 colored balls of M colors. When a ball is drawn, it is then placed back in the urn together with an
 additional new ball of the same color. Let $\mathbf{U}_i = \{u_{i,1}, u_{i,2}, \dots, u_{i,M}\}$ where $u_{i,j}$ is the number of balls
 256 of the j -th color in the urn after i draws. Let $S_{i,j} = 1$ when drawing a j -colored ball on the i -th draw,
 and 0 otherwise. The probability that $S_{i,j} = 1$ given \mathbf{U}_{i-1} is

$$258 \quad P(S_{i,j} = 1 \mid \mathbf{U}_{i-1}) = \frac{u_{i-1,j}}{\sum_{m=1}^M u_{i-1,m}} = \frac{o_j + w_{i-1,j}}{\sum_{m=1}^M o_m + w_{i-1,m}} = \frac{o_j + w_{i-1,j}}{i-1 + \sum_{m=1}^M o_m}, \quad (15)$$

where o_j is the initial number of balls of color j in the urn, and $w_{i,j}$ is the cumulative number of new
 260 balls that were added to the urn after i draws of color j .

262 **Result 2** (Pólya urn model). *The role-model choice process, $\{\mathbf{K}_i\}_{i=1}^N$, is equivalent to a Pólya urn
 model if both the trait estimation error and the success-bias weight are constant in the population,
 264 $e_i = e$ for all $i = 1, \dots, N$ and $\alpha_{i,j} = \alpha$ for all $i, j = 1, \dots, N$.*

Proof. Write $\alpha' = \frac{\alpha}{1-\alpha}$ as the success-bias weight ratio, and $A'_j = A_j + e$. From eq. (10) and because
 266 $\sum_{j=1}^N K_{i,j} = i$, we have

$$G_{i,j} = \frac{\alpha' \beta(A'_j) + K_{i-1,j}}{\sum_{m=1}^N [\alpha' \beta(A'_m) + K_{i-1,m}]} = \frac{\alpha' \beta(A'_j) + K_{i-1,j}}{i-1 + \sum_{m=1}^N \alpha' \beta(A'_m)}. \quad (16)$$

268 Substituting $M = N$, $o_j = \alpha' \beta(A'_j)$, and $w_{i,j} = K_{i,j}$ in eq. (15) gives eq. (16), thus completing the
 proof.

270 Frigyik et al. [19, section 2] prove that the proportion of different colored balls in a *Pólya urn model*
 converges to the Dirichlet distribution as the number of draws (the population size, N , in our model)
 272 approaches infinity, based on the *Martingale Convergence Theorem* [20]. We therefore have an ap-
 proximation for the relative influence each role-model has when evaluated by copiers. Thus, choosing
 274 the role-models for all copiers is equivalent to drawing from a multinomial distribution where the
 parameters are the modified weights from a Dirichlet distribution and we have the following corollary.
 276

Corollary 2 (Dirichlet-Multinomial distribution approximation). *The number of copiers of each role-
 278 model approximates a Dirichlet-Multinomial distribution, $\mathbf{K}_N \sim \text{DirMul}(N, \mathbf{G}_1)$, under the conditions
 of Result 2.*

280 **Numerical validation.** We next validated the DMD approximation of our model and tested its
 sensitivity to the assumptions ($e_i = e$ and $\alpha_i = \alpha$ for $i = 1, \dots, N$) by comparing results of stochastic
 282 simulations of our model (eq. (11)) with the DMD approximation (Corollary 2). We used a relatively

small population size, $N = 100$, thus validating that the approximation is in good agreement even for
 284 small N , despite the assumption of large N in the proof by Frigayik et al. [19, section 2]. First, we
 computed an observed distribution of the number of copiers from the average empirical distribution
 286 of multiple simulations. We then compared this observed distribution with the expected theoretical
 DMD (Figure S3A). The difference in distributions was not perceived when plotting both distributions
 288 on the same figure, so we used the difference instead. The maximum difference is 0.5 role-models,
 which indicates a very good fit. In addition, we tested the likelihood of the observed data to be drawn
 290 from the DMD, against a shuffle of the parameters vector of the DMD itself (Figure S3B). We see that
 the negative log likelihood of the observed data is much higher than any other shuffled version of the
 292 parameters vector, strongly supporting our approximation.

Next, we examined the fixation probability and fixation time of a ‘successful’ phenotype \hat{A} (i.e., that
 294 is favored by success bias) when invading a population of phenotype A and compared results from the
 full model and the DMD approximation. Thus, we assume the population has a single individual with
 296 phenotype \hat{A} and $N - 1$ individuals with phenotype A . We find that the number of simulations needed
 to sufficiently approximate our model with the DMD approximation is roughly 1,000 (Figure S4).
 298 We examined the robustness of the DMD approximation to relaxing the following assumptions. First,
 we relaxed our assumption of no estimation error e . Estimation error in the original model was
 300 drawn from a normal distribution, and added to the trait value before evaluation of the success ‘bias’
 ($A_{i,j} = A_j + e_i$). When estimation error is applied, we sample e_i for each copier i from a normal
 302 distribution with expected value zero and variance η^2 . Even when the estimation error variance is 0.1,
 both the fixation probability and fixation time DMD approximations are accurate (Figure S5). We
 304 also relaxed our assumption of a uniform bias weight α (i.e., $\alpha_i = \alpha$). We allowed α to vary in the
 population, drawing α_j for each role-model j from a normal distribution such that $\alpha_j \sim N(0.5, \epsilon)$
 306 where ϵ is between 10^{-7} and 10^{-1} . We found again that results of the DMD approximation are similar
 to those from stochastic simulations of the full model (Figure S6).

308 **Fixation probability and time**

After finding that the DMD is a good approximation of the (within-generation) role-model choice
 310 process, we turn our attention to the (between-generation) evolutionary dynamics. We focus on the
 fixation probability and conditional fixation time (conditioned on the population reaching fixation)
 312 of a ‘successful’ phenotype, using a diffusion-equation approximation approach, similar to analyses
 of population-genetic models [21, 47, 48]. We are mainly interested in the effect of the success-bias
 314 weight, α , which determines the relative effect of success and prestige bias, given by eq. (10).

For simplicity, we use the dichotomous-trait model, which also assumes a constant success-bias
 316 weight $\alpha_{i,j} = \alpha$, and we do not include trait estimation error in this analysis, i.e., $e_i = 0$. As shown
 above, transmission in our model is approximately Dirichlet-Multinomial distributed (Corollary 2
 318 and eq. (16)). We focus on two scenarios: the first scenario is of a ‘constant environment’ in which
 the same phenotype, \hat{A} , is always favored by success bias; the second scenario is of a ‘changing
 320 environment’ in which the phenotype favored by success bias cycles between the invading phenotype
 \hat{A} and the resident phenotype A (i.e., \hat{A} starts as the rare phenotype).

322 **Drift and diffusion terms in a constant environment.** We start by finding the expectation and
 variance of the change in frequency from one generation to the next, which are the drift and diffusion
 324 terms of the diffusion equation. Let x and x' be the frequency of phenotype \hat{A} in a population with
 N individuals in the current and next generation, respectively. We set β to be the success bias of
 326 phenotype A relative to phenotype \hat{A} , such that $\beta = \beta(A)/\beta(\hat{A}) < 1$. Then (see Appendix B for
 derivation),

$$328 \quad \begin{aligned} E[x' - x] &= x(1 - x)(1 - \beta) + o(1 - \beta) , \\ V(x' - x) &= x(1 - x) \left(\frac{1}{\alpha N + (1 - \alpha)} \right) + o \left(\frac{1}{\alpha N + (1 - \alpha)} \right) . \end{aligned} \quad (17)$$

This analysis gives an interesting result relating the parameters α and β to parameters of the clas-
 330 sical Wright-Fisher model from population genetics: the selection coefficient s , a measure of the
 effect of natural selection on the change in frequency of genotypes, and the effective population size,
 332 N_e , a measure of the effect of random genetic drift on the change in frequency of genotypes. In a
 diffusion-equation approximation of the classical Wright-Fisher model, the expectation and variance
 334 of the change in frequency are $E[x' - x] = sx(1 - x) + o(s)$ and $V[x' - x] = x(1 - x)/N_e$ [21, eq. 7],
 respectively. Therefore, we have the following result.

336

Result 3 (Effective selection coefficient and population size). *The effective selection coefficient s
 338 and effective population size N_e can be written in terms of the success coefficient β (eq. (5)), the
 success-bias weight α (eq. (10)), and the population size N as*

$$340 \quad s = 1 - \beta = \frac{\beta(\hat{A}) - \beta(A)}{\beta(\hat{A})}, \quad N_e = \alpha N + (1 - \alpha) . \quad (18)$$

Note that when $N \gg 1$, $N_e \approx \alpha N$, resulting in a very convenient expression.

342

Using our effective selection coefficient, $s = 1 - \beta$, and effective population size, N_e , with the
 344 population-genetics fixation probability approximation given by Kimura [21, eq. 8], we obtain the
 following result.

346

Result 4 (Fixation probability). *The fixation probability of an invading phenotype favored by success
 348 bias is approximately*

$$\pi(x) = \frac{1 - e^{-2(1-\beta)N_e x}}{1 - e^{-2(1-\beta)N_e}} , \quad (19)$$

350 where x is the initial frequency of the invading phenotype.

Similarly, we can use $1 - \beta$ and N_e in the population-genetics fixation time approximation given by
 352 [47, eq. 17].

354 **Result 5** (Fixation time). *The expected fixation time (conditioned on fixation) from an initial frequency*
 x is approximately

$$356 \quad T(x) = J_1(x) + \frac{1 - \pi(x)}{\pi(x)} \cdot J_2(x), \quad (20)$$

where $N_e = \alpha N + (1 - \alpha)$, $S = N_e(1 - \beta)$, and

$$358 \quad \begin{aligned} J_1(x) &= \frac{-1}{(1 - \beta)(e^{-2S} - 1)} \int_x^1 \frac{1 - e^{2S\xi} - e^{-2S(1-\xi)} + e^{-2S}}{\xi(1 - \xi)} d\xi, \\ J_2(x) &= \frac{-1}{(1 - \beta)(e^{-2S} - 1)} \int_0^x \frac{(1 - e^{2S\xi})(e^{-2S\xi} - 1)}{\xi(1 - \xi)} d\xi. \end{aligned} \quad (21)$$

Note that these integrals cannot be solved in closed form, and are estimated numerically.

360 Results 4-5 lead to the following observations. First, the fixation probability increases (Figure 1B) and
the fixation time decreases (Figure 1D) as a function of the success coefficient $1 - \beta$, which acts as an
362 effective selection coefficient. Second, the fixation probability increases with the success-bias weight
 α (Figure 1A), reaching a maximum at $2(1 - \beta) = 2s$ when there is no prestige bias ($\alpha = 1$), in which
364 case the effective population size equals the actual population size (eq. (18)) Third, and in contrast,
the fixation time conditional on fixation is actually *shorter* with low values of α , that is, when prestige
366 bias is strong (Figure 1D). This is because prestige bias accelerates the evolutionary dynamics due to
a *rich-get-richer* process. Thus, when fixation occurs with strong prestige bias, it occurs faster than it
368 does with strong success bias.

Numerical validation. We compare our approximations (eqs. (19) and (20)) with results of sim-
370 ulations of our dichotomous model using various α and β values, as well as simulations of the
Wright-Fisher model, using the effective selection coefficient, $1 - \beta$, and effective population size,
372 $N_e = \alpha N + (1 - \alpha)$. We find that the two models have similar dynamics, and both are well approximated
by our approximations (Figure 1).

374 **Changing environment** . After finding a good approximation in a constant environment, where
the ‘successful’ trait is always \hat{A} , we proceeded to find an approximation for a periodically changing
376 environment. Following Ram et al. [23], we denote k as the number of generations in which the
invading phenotype is favored by success bias, and l as the number of generations in which the resi-
378 dent phenotype is favored by success bias. Thus, during the first k generations of the environmental
cycle, $\beta = \frac{\beta(A)}{\beta(\hat{A})} < 1$, where \hat{A} is the invading phenotype. During the following l generations of the
380 environmental cycle, the phenotype favored by success bias is switched, such that $\frac{\beta(A)}{\beta(\hat{A})} > 1$. We
then proceed to find expressions for the expectation and variance of the change in the frequency of
382 phenotype \hat{A} after $n = k + l$ generations. The proof is in Appendix C.

384 **Drift and diffusion terms in a changing environment.** Let x be the initial frequency of the invading
phenotype and X_t the number of individuals with that phenotype after n generations. Then,

$$386 \quad E[X_n/N - x] \simeq x(1 - x)S_n/N_e, \quad \text{and} \quad V(X_n/N - x) \simeq nx(1 - x)/N_e, \quad (22)$$

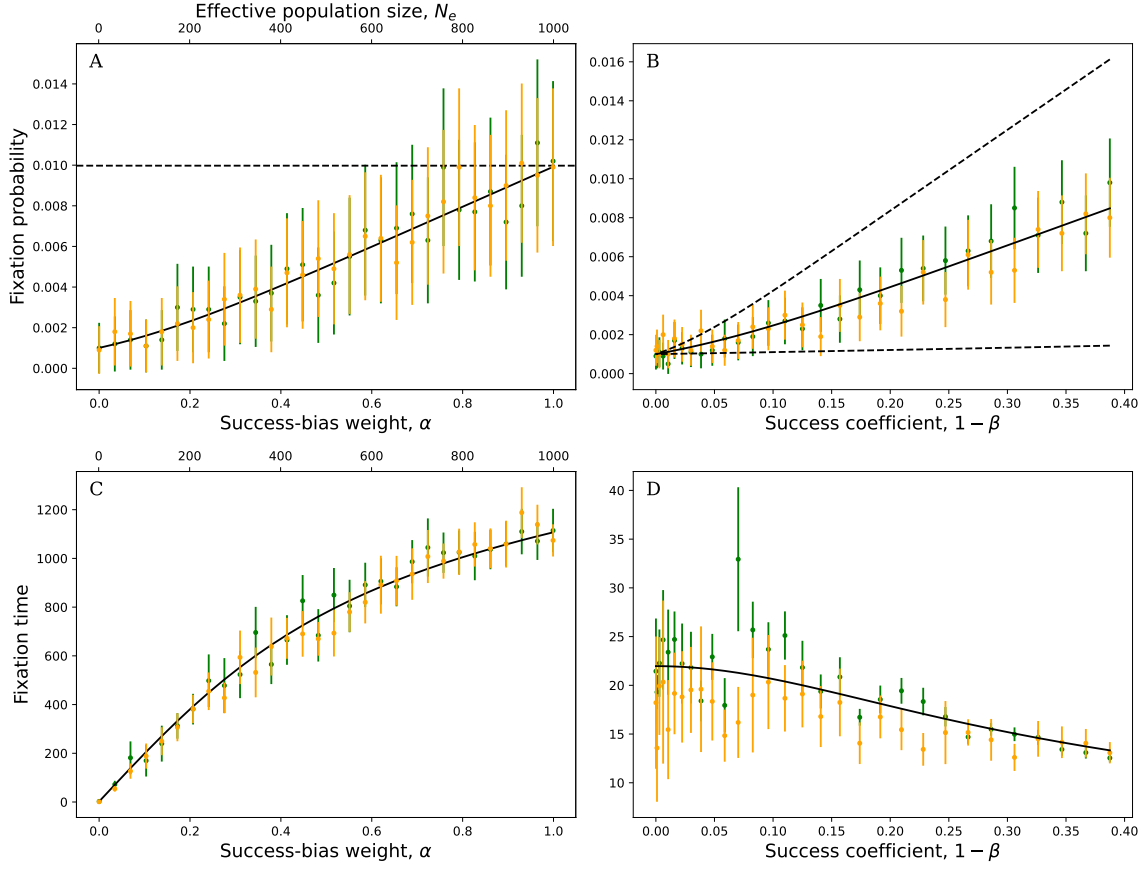

Figure 1: Fixation probability and time in a constant environment. The effect of the success-bias weight α (bottom x-axis) and effective population size, N_e , (top x-axis) on the fixation probability (A) and the conditional fixation time (B), and the effect of the success coefficient, or effective selection coefficient, $1 - \beta$, on the fixation probability (B) and the conditional fixation time (D). Our approximation (black; eq. (19)) agrees with both DMD simulations (green) and Wright-Fisher simulations (orange). Panel A shows a dashed line at $2(1 - \beta)$, which is reached by our approximation when $\alpha = 1$. Panel B has three lines: solid for our approximation for $\alpha = 0.01$, and dashed for $\alpha = 0$ (bottom) and $\alpha = 0.02$ (top). Markers are averages of 10,000 simulations. Error bars show 95% confidence intervals for panels A and B and 75% for panels C and D. Here, population size is $N = 1,000$; In panels A and B, $A = 0.9$, $\hat{A} = 1$ ($1 - \beta = s = 0.005$); In panels C and D, $0.01 < A < 0.99$, and $\hat{A} = 1$, which determines $1 - \beta$ via $\beta = \beta(A)/\beta(\hat{A})$ and eq. (5), $\alpha = 0.01$.

where $S_n = \sum_{t=1}^n N(1 - \beta_t)$ and β_t is $\beta(A)$ at generation t .

388 Note that here, we have the ‘average selection coefficient’ during a cycle of n generations, S_n/n as the
 390 selection coefficient in eq. (19). Using the drift and diffusion terms and following Ram et al. [23], we
 can approximate the fixation probability in a changing environment.

392 **Result 6** (Fixation probability in a periodically changing environment). *The fixation probability of an
 invading phenotype under periodical environmental changes is approximately*

$$394 \quad \tilde{\pi}(x) = \frac{1 - e^{-2 \frac{S_n}{n} N_e x}}{1 - e^{-2 \frac{S_n}{n} N_e}}. \quad (23)$$

where x is the initial frequency of the invading phenotype.

396 Importantly, the average selection coefficient, S_n/n , has the same sign as $k - l$. Therefore, when
 398 $k > l$, the fixation probability will increase with the success-bias weight α (similar to a constant
 environment, Figure 1A), and when $k < l$, the fixation probability will decrease with the success-bias
 weight α (Figure 2A). Furthermore, the fixation probability increases with the success coefficient
 400 $(1 - \beta)$, Figure 2B; see below for how simulation results compare to the constant environment and
 changing environment approximations) and becomes larger as $k - l$ increases, i.e., as the number of
 402 generations in which the invading phenotype is favored increases (Figure 2C).

Numerical validation. To validate the approximation for the fixation probability in a changing
 404 environment (eq. (23)), we compare it to results of simulations that use the DMD approximation
 (Corollary 2). We find that the approximation fits the simulation results well for variable success-bias
 406 weights, α , which corresponds to the effective population size (Figure 2A). However, the approximation
 is more sensitive to the value of the success bias coefficient β (Figure 2B). When the success coefficient
 408 $1 - \beta$ is large, the approximation can break, as the fixation time can be lower than the number of
 generations in the cycle, n (see Figure 1D), and therefore the average selection coefficient, S_n/n is not
 410 a good estimate of the effective selection coefficient. We also changed the ratio between the number
 of cycles where \hat{A} is favored and disfavored. We found that the approximation fits well regardless of
 412 the ratio, and that for a large $k - l$ difference (with a constant cycle length, $n = k + l = 100$), the
 changing environment approximation (eq. (23)) converges to the constant environment approximation
 414 (eq. (19); Figure 2C). This makes sense as a constant environment can be viewed as an environment
 in which the cycle length is longer than the fixation time.

Figure 2: Fixation probability in a changing environment, $k < l$. (A) Fixation probability decreases with the success-bias weight (bottom x-axis) and effective population size (top x-axis). The approximation (blue; eq. (23)) agrees with simulation results (orange). (B) Fixation probability increases with the success coefficient, β . When success bias is large ($1 - \beta > 0.1$), simulation results (orange) are underestimated by the changing environment approximation (blue; eq. (23)). With even larger success bias ($1 - \beta > 0.35$), even the constant environment approximation (green; eq. (19)) slightly underestimates simulation results, likely because the diffusion equation approximation assumes weak ‘selection’. (C) The approximation (blue) is robust to changes in environmental cycle length, as it agrees with simulations (orange) for different sizes of the changing environment cycle, where k and l are the number of generations each trait value is under success bias. When $k > l$, the approximation and the simulations are both very close to the constant environment approximation (green), because the more generations the rare phenotype is favored, the more similar it is to the constant environment model, where it is always favored by the success bias. Markers show average of 10,000 simulations, error bars show 75% (panels A and C) and 95% (panel B) confidence intervals. See Figure S7 for the scenario where $k > l$. Here, population size is $N = 1,000$; In panel A, $A = 0.9$, $\hat{A} = 1$ ($1 - \beta = s = 0.005$), $k = 20$, and $l = 80$; In panel B, $0.01 < A < 0.99$, and $\hat{A} = 1$, which determines $1 - \beta$ via $\beta = \beta(A)/\beta(\hat{A})$ and eq. (5), $k = 20$, and $l = 80$, $\alpha = 0.1$; In panel C, $A = 0.8$, $\hat{A} = 1$ ($1 - \beta = s = 0.0198$), $\alpha = 0.1$.

416 Optimal success-bias weight

In results 2-6, we assumed that the bias weight α is homogeneous in the population and constant, that is, it does not depend on any specific context. However, rational individuals could potentially adjust their bias weight to balance between success and prestige bias depending on their context, such as the number of individuals who have already chosen a role model. Therefore, we examined what happens in the continuous-trait model if the i -th copier evaluates its own optimal success-bias weight, α_i^* , which minimizes the expected squared error between the chosen trait value and the ‘successful’ trait value \hat{A} ,

$$424 \quad \alpha_i^* = \operatorname{argmin} \sum_{j=1}^N \frac{\alpha A_j + (1 - \alpha) K_{i-1,j}}{\sum_{l=1}^N \alpha A_l + (1 - \alpha) K_{i-1,l}} (\hat{A} - A_j)^2, \quad (24)$$

where A_j is the trait of role-model j and $K_{i-1,j}$ is the number of copiers that already chose role-model j by the time the i -th copier chooses a role-model. Simply put, each copier i estimates what success-bias weight α_i^* will result in copying a trait that is most similar to the ‘successful’ trait value \hat{A} . Indeed, if the trait value is correlated with fitness, the optimal success-bias weight would increase the fitness of individuals. However, here we ignore the effects of natural selection, focusing instead on selectively neutral traits.

We find that when copiers choose their success-bias weight according to eq. (24), it quickly decreases with the number of copiers that have already chosen a role-model and then stays at what appears to be an equilibrium (Figure 3). Moreover, the estimation error is much lower compared to a constant success-bias weight, which gives roughly the same high estimation error to all copiers (compare Figure 3B and C): in this example, the optimal success-bias weight gives an estimation error (difference between the chosen and ‘successful’ trait) that converges to 0.046, whereas a constant success-bias weight gives values greater than 0.74.

438 Discussion

Some cultural traits or cultural role-models may be copied more often than others due to transmission biases. One such bias is success bias, in which copiers are more likely to copy a successful role-model. It has been suggested that because it is hard to estimate success, a more common bias is a bias towards role-models *perceived* to be successful. This perceived success can be determined by performance with respect to another trait, i.e., *indirect success* [7, 26], or by “the amount of voluntary deference and attention received by models” [1], i.e., *prestige* [28, 32, 63] (but see Chellappoo [2] for a critical examination of the concept of prestige).

We developed two cultural-evolutionary models, one with continuous and one with dichotomous trait values. Our models include both indirect success and prestige biases, where the latter is a bias towards role-models with many copiers. We model these biases using a stochastic role-model choice process: each copier, in turn, randomly chooses a role-model, and this choice is affected both by the estimated success of each potential role-model and the number of copiers that already chose each role-model (eq. 10). Hence, our models have two “nested” stochastic processes: the role-model

Figure 3: Advantage of an optimal success-bias weight. Both success-bias weight α (A) and estimation error (B) decrease during the role-model choosing process (within a single generation), demonstrating that prestige becomes more favored by copiers as more copiers have made their choice. However, when α is homogeneous (C), the mean estimation error does not decrease, regardless of α or η . The mean estimation error in the homogeneous α model is larger by a factor of 10 than the optimal α model. Here "Copier" of the x-axis is the index of the choosing copier, population size $N = 200$; estimation error is normally distributed $e \sim N(0, \eta^2)$ with standard deviation $\eta = 0.0001$ (blue), 0.001 (orange), 0.01 (green), markers are average of 300 simulations.

choice process within each generation, and the cultural-evolutionary process between generations. To simplify the mathematical and computational analysis, we developed analytic approximations for the role-model choice process using the *generalized binomial distribution* (GBD, Result 1) and the *Dirichlet-Multinomial distribution* (DMD, Corollary 2). The latter is especially useful, as it approximates the entire role-model choice process and only requires us to assume that the relative effect of success and prestige is a characteristic of the role-model and not the copier.

Analyzing the dichotomous-trait model using the DMD approximation, we found approximations for the fixation probability and fixation time of a cultural trait under biased transmission in a constant environment. Our approximations are similar to Kimura's evolutionary-genetic approximations, in that (i) the strength of success bias towards the invading cultural trait, $\beta = \beta(\hat{A})/\beta(A)$, is equivalent to the selection coefficient in favor of a beneficial allele, s , and (ii) decreasing the relative weight of success versus prestige bias, α , decreases the effective population size, N_e . Therefore, when either

464 α or $1 - \beta$ increases, the fixation probability increases (Figure 1A and Figure 1B). However, while
increasing the $s = 1 - \beta$ decreases the fixation time, as ‘selection’ is stronger (Figure 1D), increasing
466 the success-bias weight α increases the conditional fixation time (Figure 1C). This is because, when
the invading phenotype manages to fix in a population with strong prestige bias, it will do so faster
468 compared to a population with weak prestige bias, as strong prestige leads to a *rich-getting-richer*
process.

470 We also analyzed the dichotomous–trait model in a periodically changing environment in which the
identity of the success-biased trait switches after a fixed amount of generations (Figure 2). We again
472 derive an approximation for the fixation probability, which works well when the success coefficient
 $1 - \beta$ is low. In the case of a changing environment, two key values are the number of generations k
474 and l in which the invading and resident traits are favored by success bias, respectively. When $k > l$,
strong success (high α) will increase the fixation probability (Figure S7), but when $k < l$, strong
476 prestige (low α) will increase the fixation probability (Figure 2A). This is because prestige accelerates
the evolutionary dynamics, which allows the invading trait to fix before the environment changes to
478 favor the resident trait. In all cases increasing the success coefficient $1 - \beta$, which is equivalent to
increasing the strength of selection, will increase the fixation probability (Figure 2B).

480 Lastly, we examined a scenario in which copiers can adjust their success-bias weight, α , to minimize
their copying error, i.e., copy trait values closer to the optimal value. We found that as the role-model
482 choice process proceeds (that is, more copiers make their choices), both the success-bias weight
(adjusted by copiers) and the estimation error decrease. The latter is significantly lower than in a
484 population using a constant, fixed success-bias weight, regardless of the value of the constant weight
(Figure 3). This suggests that the later a copier makes its choice, the more it should rely on choices
486 of previous copiers (prestige), and the less it should rely on its own estimation of the success of
role-models. The rationale, then, is that the more information a copier has, e.g., by using others as
488 information sources, the more informative and effective his choice can be.

Chudek et al. [32] report the first direct tests in children that suggest the existence of prestige bias,
490 defined as the tendency to learn from individuals to whom others have preferentially attended, learned,
or deferred. Their definition of prestige is similar to ours. They showed that the odds of 3-4 years-old
492 children learning from an adult role-model to whom bystanders had previously preferentially attended
for 10 seconds were more than twice those of learning from a role model whom bystanders ignored.
494 They also note that prestige effects are domain sensitive: they found that prestigious role-models were
attended more when demonstrating artifact use, whereas role-models presenting food preferences had
496 less attendants, suggesting that the domain itself (artifact use vs. food preference) can affect the
attendance, and hence the prestige of the role-model. This led to the suggestion that when the trait is
498 costly to learn individually, prestige will have a stronger bias [32]. It would be interesting to include
costs in our model to try and observe these effects and dynamics in a large population.

500 According to Henrich and Broesch [26], natural selection has favored the emergence of psychological
biases for learning from those individuals most likely to possess adaptive information. The authors
502 studied Fijian villages to examine if and how such biases emerge in a small-scale society. They

found that Fijian villagers are more likely to learn from role-models perceived as more successful/knowledgeable, both within and across domains. Their research thus suggests that copying from those perceived as successful, rather than who are actually successful, is a common phenomenon. They show that the social networks representing copier–role-model relationships are centralized, which is consistent with the prediction that people substantially share notions about who is a good cultural model, but that individuals’ role-model selections are influenced by multiple factors.

Dunbar [31] hypothesized that larger, more complex brains can store and manage more information and in turn, this information can support the costs of a larger brain. Following this, Muthukrishnan and Henrich [30] suggested that prestige can directly affect human physical evolution. They present a concept called *cultural brains*—brains that evolved primarily for the acquisition of adaptive knowledge. They then develop a model that predicts a strong relationship between brain size and group size, because group size also provides access to more adaptive knowledge. They also presented the *cumulative cultural brain* hypothesis, which proposes that human brains have evolved with an ability and tendency for selective, high-fidelity social learning. As part of this process, there are a variety of strategies and biases that have evolved to hone in on the most adaptive knowledge. These strategies and biases include direct and indirect cues of the popularity of cultural traits (e.g. success and prestige biases). They suggest that one of the reasons for the extreme increase in brain size in humans is the ability to ‘cheaply’ acquire adaptive knowledge via transmission biases such as prestige.

Prestige bias can help to cheaply estimate and acquire knowledge, which may facilitate survival and reproduction. However, it is not always the case, and there could be negative repercussions to this bias, such as invasion of maladaptive traits. Takahashi and Ihara [29] mention that social learning not only takes the form of random copying of other individuals, but also involves learners’ choice of what to learn and from whom to learn. They suggest a best-of- k model where an individual samples k role-models and chooses the one he deems most "successful". They mention that a previous mathematical analysis has shown that it may sometimes result in maladaptive cultural evolution when the payoffs associated with cultural variants vary stochastically. In such a case, learners may be selectively disfavored and in the long run replaced by unbiased learners, who simply copy someone chosen at random. They developed new mathematical models that are simpler and mathematically tractable. They found that best-of- k learning, unlike unbiased learning, can facilitate the invasion of an on average inferior variant that sometimes gives a very high payoff (see Fogarty et al. [57] and references there). Our model, which includes both success and prestige bias, is consistent with this claim. When a maladaptive trait is ‘piggybacking’ on a role-model with high influence (joint effect of success and prestige), the former could spread in the population. In addition, best-of- k learning can be stable against invasion by unbiased learning if social learning is sometimes combined with individual learning [29]. Our model includes only social learning, and not individual learning, but it could be interesting to combine it with individual learning and see how it affects the dynamics.

Prestige bias can also accelerate reversal of harmful traditions such as child marriage and domestic violence. Efferson et al. [27] suggest a *spillover* mechanism, in which an intervention affects a large enough group in a target population, so that others not included in the intervention also change their

542 behavior. They find that there are individuals who act as *agents*, who are often observed, and therefore
they are ideal targets for interventions. This is similar to prestigious role-models in our model, which
544 are copied more often, and will therefore spread their trait faster and wider in the population. They
also suggest a way to use this phenomenon to change existing traditions in a population. It is very
546 clear however, that just as it can be used to end harmful traditions, the same agents could start harmful
traditions.

548 Others have analyzed models with interactions between different transmission biases. Hong [59]
studied a model with both conformity and success bias (which he calls ‘payoff bias’). He showed
550 that an intermediate level of conformity bias—not too little but not too much—can be adaptive and
evolve to prevent invasion of low-success traits while allowing the invasion of high-success traits (for
552 another example of adaptive filtering, see [60]). Similar to our model (eq. (10)), Hong [59] also
additively combined the two transmission biases (his eq. 1). However, transmission biases can be
554 combined in many ways. For example, Denton et al. [37] combined frequency-dependent bias and
genetically determined content bias multiplicatively (their eq. 1). Ammar et al. [61] studied a model
556 in which individuals have a repertoire of cultural variants to choose from, and both variant choice
and transmission via social learning are success-biased. Moreover, they also included the possibility
558 to ‘forget’ infrequently used variants; therefore, because usage is success-biased, memory is also
success-biased. It remains to be seen how different assumptions on the mechanisms of learning and
560 forgetting affect the evolutionary dynamics under different and interacting transmission biases.

One path forward is an analysis of the dynamics of the optimal success-bias weight model, in which
562 every copier chooses its α . It would be interesting to see if the mean estimation error and the
varying weight, α^* , converge to specific values, and how they are affected by the model parameters. It
564 may also be possible to relax the assumptions required for our approximations, such as homogeneous
estimation error and success-bias weight. Another possibility is to model prestige bias in a different
566 way. For example, using a Moran model [62], one could build model with overlapping generations,
which would mix the within-generation model role-model choice process and the between-generation
568 evolutionary dynamics. Lastly, it would be interesting to analyze the fixation probability and time
in the continuous model and determine how the results compare to those from the dichotomous
570 model.

Another way to expand our model is to account for the two types of prestige or leadership suggested by
572 Van Vugt and Smith [25] that are attributed to Confucius and Machiavelli. Confucius viewed leaders as
role-models who exercise influence through possessing superior knowledge, skills, and (outstanding)
574 personal qualities. This fits the success bias in our model. In contrast, Machiavelli viewed leaders
as rulers who exercise influence by imposing costs through (the threat of) punishment and violence.
576 Van Vugt and Smith suggest that these opposing views are both partially supported by the available
evidence but each one on its own offers an incomplete view of the complex and dynamic concept of
578 leadership. Henrich and Gil-White [28] have suggested a similar distinction between ‘prestige and
‘dominance’, or between ‘persuasion’ and ‘force’. Several adjustments could be made so that our
580 model reflects these leadership styles, such as assuming there is a correlation between phenotype and

leadership style. The resulting cultural-evolutionary dynamics and their dependence on the costs and
582 benefits are intriguing.

Conclusions. We studied a model of cultural evolution under two transmission biases: the commonly
584 studied success bias, together with prestige bias, which has so far received less attention by modelers.
We found approximations for this complex dynamics. We then showed that success bias affects the
586 evolutionary dynamics much like natural selection does, whereas prestige bias has a similar effect to
random genetic drift. We also find a clear advantage to individuals that can choose the relative weight
588 of the two biases.

Appendices

Appendix A General binomial distribution approximation

Proving $E[K_{Nj}] = \alpha_j \cdot \beta(A_j + e) / \overline{\alpha \cdot \beta(A + e)}$, where the average in the denominator is over the role-models index, j .

Proof. The initial influence of role-model j based on eq. (10) is

$$G_{1,j} = \frac{\alpha_j \cdot \beta(A_j + e)}{\sum_{m=1}^N \alpha_m \cdot \beta(A_m + e)} . \quad (A1)$$

The denominator of eq. (A1) can also be formulated as:

$$\sum_{m=1}^N \alpha_m \beta(A_m + e) = N \cdot \overline{\alpha \cdot \beta(A + e)} , \quad (A2)$$

where $\overline{\alpha \cdot \beta(A + e)}$ is the mean value of $\alpha_m \cdot \beta(A_m + e)$. Using eq. (A2) and **Corollary 1** we get,

$$E[K_{N,j}] = \alpha_j \cdot \beta(A_j + e) \left/ \overline{\alpha \cdot \beta(A + e)} \right. , \quad (A3)$$

Appendix B Drift and diffusion in a constant environment

Proving drift and diffusion terms in a constant environment. Let x and x' be the frequency of type \hat{A} in a population with N individuals in the current and next generation, and β be the success coefficient of phenotype A , $\beta = \beta(A) < \beta(\hat{A}) = 1$. Then,

$$E[x' - x] \approx x(1 - x)(1 - \beta) , \quad V(x' - x) \approx x(1 - x) \left(\frac{1}{\alpha N + (1 - \alpha)} \right) .$$

Proof. Let X be the number of individuals of type \hat{A} such that $x = X/N$. X' is the number of individuals with \hat{A} in the next generation. The expected number of individuals is (due to the DM approximation),

$$E[X'] = N \frac{\alpha_1}{\alpha_1 + \alpha_2} , \quad (B1)$$

where $\alpha_1 = \alpha'X$ and $\alpha_2 = \alpha'(N - X)\beta$, from eq. (11). To use frequencies instead of counts, $E[x'] = E[X'/N] = \frac{1}{N}E[X']$. Putting it together,

$$\begin{aligned} E[x'] &= \frac{1}{N}N \frac{\alpha'xN}{\alpha'xN + \alpha'N(1-x)\beta} = \frac{x}{x + (1-x)\beta} \\ &= \frac{x}{x + (1-x) - (1-x) + (1-x)\beta} = x \frac{1}{1 - (1-x)(1-\beta)} \\ &= x(1 + (1-x)(1-\beta) + o(1-\beta)) = x + x(1-x)(1-\beta) + o(1-\beta), \end{aligned} \quad (\text{B2})$$

following Durrett [22, p. 253, ch 7.2] and because $1/(1-y) = 1 + y + y^2 + \dots$

We therefore have

$$E[x' - x] = E[x'] - E[x] = x(1-x)(1-\beta) + o(1-\beta), \quad (\text{B3})$$

which gives us the drift term of the diffusion equation.

Using the variance of the DMD,

$$V(X') = N \frac{\alpha_1}{\alpha_1 + \alpha_2} \left(1 - \frac{\alpha_1}{\alpha_1 + \alpha_2}\right) \left(\frac{N + \alpha_1 + \alpha_2}{1 + \alpha_1 + \alpha_2}\right). \quad (\text{B4})$$

Again, we want to use frequencies so we have $V(X'/N) = \frac{1}{N^2}V(X')$. Putting it together with our model notations,

$$V(x') = \frac{1}{N^2}N \frac{x}{x + (1-x)\beta} \left(1 - \frac{x}{x + (1-x)\beta}\right) \left(\frac{N + \alpha'xN + \alpha'N(1-x)\beta}{1 + \alpha'xN + \alpha'N(1-x)\beta}\right). \quad (\text{B5})$$

Following Durrett [22, ch 7.2], we assume $\beta \approx 1$, such that

$$\frac{x}{x + (1-x)\beta} \approx x \quad (\text{B6})$$

and for the entire variance expression we get

$$V(x') \approx \frac{1}{N}x(1-x) \left(\frac{N + \alpha'xN + \alpha'N - \alpha'xN}{1 + \alpha'xN + \alpha'N - \alpha'xN}\right) = x(1-x) \left(\frac{1 + \alpha'}{1 + \alpha'N}\right). \quad (\text{B7})$$

The current frequency x is a given, such that $V(x) = 0$, and therefore

$$V(x' - x) = V(x') - V(x) \approx x(1-x) \left(\frac{1 + \alpha'}{1 + \alpha'N}\right). \quad (\text{B8})$$

α' is the odds ratio of the bias weight,

$$\alpha' = \frac{\alpha}{1 - \alpha}. \quad (\text{B9})$$

Combining eq. (B8) and eq. (B9) we get:

$$V(x' - x) \approx x(1 - x) \left(\frac{1 + \frac{\alpha}{1-\alpha}}{1 + \frac{\alpha}{1-\alpha}N} \right) = x(1 - x) \left(\frac{1}{\alpha N + (1 - \alpha)} \right). \quad (\text{B10})$$

This gives the diffusion term of the diffusion equation.

Appendix C Drift and diffusion in a changing environment

Proving drift and diffusion terms in a changing environment. Let x be the initial frequency of the invading phenotype and X_t is the number of individuals with the phenotype at time t . Then,

$$E[X_t/N - x] \simeq x(1 - x)S_t/N_e, \quad \text{and} \quad V(X_t/N - x) \simeq tx(1 - x)/N_e,$$

where $S_t = \sum_{i=1}^t N(1 - \beta_i)$.

Proof. Let $s_t = N(1 - \beta_t)$, and $S_n = \sum_{i=1}^n s_i$, where β_t is $\beta(A)$ at generation t . We prove by induction both terms in eq. (22). From eq. (B3) we know that

$$E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \middle| X_t \right] = \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) (1 - \beta_{t+1}) = \frac{1}{N} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) s_{t+1}. \quad (\text{C1})$$

Also note that using the definition of $V(y) = E[y^2] - (E[y])^2$

$$\begin{aligned} E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] &= E \left[\frac{X_t}{N} - \left(\frac{X_t}{N} \right)^2 \right] = E \left[\frac{X_t}{N} \right] - E \left[\left(\frac{X_t}{N} \right)^2 \right] \\ &= E \left[\frac{X_t}{N} \right] - V \left(\frac{X_t}{N} \right) - \left(E \left[\frac{X_t}{N} \right] \right)^2. \end{aligned} \quad (\text{C2})$$

We can now use the induction assumption of $V(\frac{X_t}{N})$ to get

$$E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] \simeq E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right) - \frac{1}{N_e} tx(1 - x). \quad (\text{C3})$$

From eq. (C1) we know that

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] &= \frac{1}{N} s_{t+1} E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] \simeq \frac{1}{N} s_{t+1} \left(E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right) - \frac{1}{N_e} tx(1 - x) \right) \\ &\simeq \frac{1}{N} s_{t+1} \cdot E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right) - \frac{1}{N_e N} s_{t+1} tx(1 - x). \end{aligned} \quad (\text{C4})$$

Now we omit $O(\frac{1}{N_e N})$ and get

$$E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] \simeq \frac{1}{N} s_{t+1} \cdot E \left[\frac{X_t}{N} \right] \left(1 - E \left[\frac{X_t}{N} \right] \right). \quad (\text{C5})$$

We now look at the induction assumption to see that

$$E \left[\frac{X_t}{N} - x \right] = E \left[\frac{X_t}{N} \right] - E[x] = E \left[\frac{X_t}{N} \right] - x , \quad (\text{C6})$$

so using the assumption we get

$$\begin{aligned} E \left[\frac{X_t}{N} \right] &\simeq \frac{1}{N} S_t x (1-x) + x , \\ 1 - E \left[\frac{X_t}{N} \right] &\simeq 1 - \frac{1}{N} S_t x (1-x) + x . \end{aligned} \quad (\text{C7})$$

We use both expressions in eq. (C5) and get

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] &\simeq \frac{1}{N} s_{t+1} \left(\frac{1}{N} S_t x (1-x) + x \right) \left(1 - \frac{1}{N} S_t x (1-x) + x \right) \\ &\simeq \frac{1}{N} s_{t+1} \cdot x (1-x) , \end{aligned} \quad (\text{C8})$$

after again omitting $O(\frac{1}{N^2})$ terms. To conclude the proof, we note that

$$E \left[\frac{X_{t+1}}{N} - x \right] = E \left[\frac{X_{t+1}}{N} - \frac{X_t}{N} \right] + E \left[\frac{X_t}{N} - x \right] , \quad (\text{C9})$$

so again using the induction assumption, together with eq. (C8) we get

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} - x \right] &\simeq \frac{1}{N} s_{t+1} \cdot x (1-x) + \frac{1}{N} S_t \cdot x (1-x) \\ &\simeq \frac{1}{N} x (1-x) (S_t + s_{t+1}) \simeq \frac{1}{N} S_{t+1} x (1-x) , \end{aligned} \quad (\text{C10})$$

which proves the drift term.

For the diffusion term, we use a property of variance,

$$V \left(\frac{X_{t+1}}{N} \right) = E \left[V \left(\frac{X_{t+1}}{N} \middle| X_t \right) \right] + V \left(E \left[\frac{X_{t+1}}{N} \middle| X_t \right] \right) . \quad (\text{C11})$$

Using eq. (C1) we see that

$$\begin{aligned} E \left[\frac{X_{t+1}}{N} \middle| X_t \right] - E \left[\frac{X_t}{N} \middle| X_t \right] &= \frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \\ E \left[\frac{X_{t+1}}{N} \middle| X_t \right] &= \frac{X_t}{N} + \frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) . \end{aligned} \quad (\text{C12})$$

Using eq. (B10) we get

$$V \left(\frac{X_{t+1}}{N} \middle| X_t \right) = \frac{1}{N_e} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) , \quad (\text{C13})$$

and using the equation $y'(1 - y') \simeq y(1 - y)$ on the first part of eq. (C11) we get

$$E \left[V \left(\frac{X_{t+1}}{N} \middle| X_t \right) \right] = \frac{1}{N_e} E \left[\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right] \simeq \frac{1}{N_e} x(1 - x) . \quad (\text{C14})$$

Moving on to simplify the second part of eq. (C11) using eq. (C12),

$$V \left(E \left[\frac{X_{t+1}}{N} \middle| X_t \right] \right) = V \left(\frac{X_t}{N} + \frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right) \quad (\text{C15})$$

Now, because $\frac{X_t}{N}$ is a frequency, i.e $0 \leq X_t/N \leq 1$, we know that $V \left(\frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right) \leq \frac{1}{4}$. We therefore find that

$$V \left(\frac{1}{N} s_{t+1} \frac{X_t}{N} \left(1 - \frac{X_t}{N} \right) \right) \leq \frac{1}{4N^2} s_{t+1}^2 ; , \quad (\text{C16})$$

and so it can be ignored. Combining our equations we get

$$V \left(E \left[\frac{X_{t+1}}{N} \middle| X_t \right] \right) = V \left(\frac{X_t}{N} \right) + O \left(\frac{1}{N^2} \right) \simeq V \left(\frac{X_t}{N} \right) . \quad (\text{C17})$$

Using the induction assumption and eq. (C14),

$$V \left(\frac{X_{t+1}}{N} \right) \simeq \frac{1}{N_e} x(1 - x) + \frac{1}{N_e} t x(1 - x) \simeq \frac{1}{N_e} x(1 - x)(t + 1) \quad (\text{C18})$$

which proves the diffusion term.

Supplementary Figures

Figure S1: Example dynamics of the dichotomous model with varying bias weight. The dichotomous model is defined in eq. (11). Shown are full dynamics without DM or GBD approximations. Here, population size, $N = 1,000$; ideal phenotype value, $\hat{A} = 1$; success bias value, $\beta(A) = 0.99$; initial phenotype frequencies are 50%-50%.

Figure S2: Numerical validation of the GB approximation. The approximation (orange) fits simulation results (blue) well when using 1,000 simulations. Here, population size, $N = 2,000$; bias weight, $\alpha = 0.1$; ideal phenotype value, $\hat{A} = 1$; role-model traits $\mathbf{A} \sim N(0, 1)$; success bias value, $\beta(A) = 0.956$.

Figure S3: Numerical validation of the DM approximation. We performed computational simulations of the role-model choice process (Equation (10)) and compared the distribution of the number of copiers to simulations when using the DMD approximation (Corollary 2). **(A)** The difference between the DM distribution (orange) and the empirical distribution of the simulations (blue) is very small. **(B)** The log-likelihood of the DMD for results of the simulations (red vertical line) is much higher than the log-likelihood of permutations of simulations (blue histogram). Here, population size, $N = 100$; number of simulations, $m = 100$; phenotype values, $\hat{A} = 1$, $A \sim N(0, 1)$; success-bias weight, $\alpha = 0.5$. No estimation error or bias is applied, and traits are estimated and copied perfectly.

Figure S4: DMD approximation precision as function of number of simulations. Our DMD approximation (orange) agrees with stochastic simulation results (blue) when using 1,000 or more simulations. Both fluctuate around the analytic fixation probability approximation (black; eq. (19)). Markers are averages across simulations, error bars are 95% confidence intervals. Here, population size, $N = 1000$; success-bias weight, $\alpha = 0.5$; phenotype values, $\hat{A} = 1, A = 0.7$; success-bias value, $\beta(A) = 0.956$.

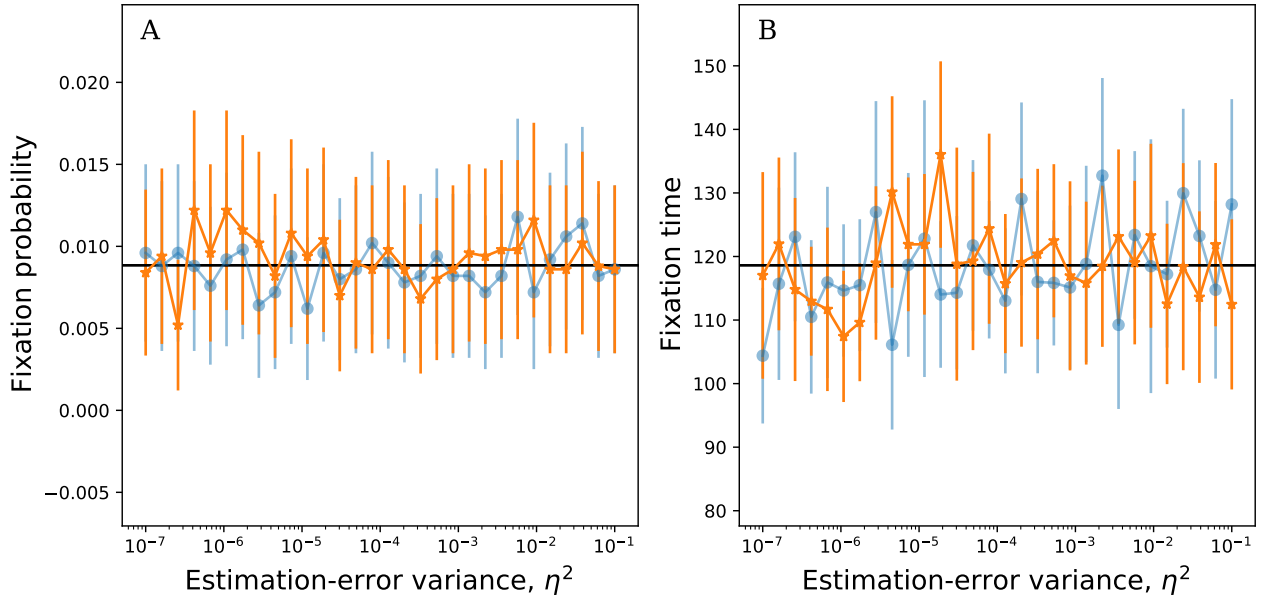

Figure S5: Robustness of DMD approximations to success estimation error. Both the DMD approximation (orange) and our approximation (black) agree with the stochastic simulations (blue), even with a high estimation error. Markers are averages across simulations, error bars are 95% confidence intervals. 5,000 simulations per data point; population size, $N = 1000$; success-bias weight, $\alpha = 0.1$; phenotype values, $\hat{A} = 1, A = 0.7$; bias strength parameter $J \sim N(1, \eta^2)$ where η^2 is on the x-axis.

Figure S6: Robustness of DM approximations to variation in the bias weight α . Fixation probability does not seem to be affected by variation in success bias weight between role-models. Thus, both the DM approximation (orange) and Kimura's equation (black line) have a good fit to results of stochastic simulations (blue). Markers for average across 5,000 simulations, error bars are 95% confidence intervals. Here, population size, $N = 1000$; success bias weight is normally distributed, $\alpha_j \sim N(0.5, \epsilon^2)$ where $10^{-7} \leq \epsilon^2 \leq 10^{-1}$; phenotype values, $\hat{A} = 1, A = 0.7$; success bias value, $\beta(A) = 0.956$.

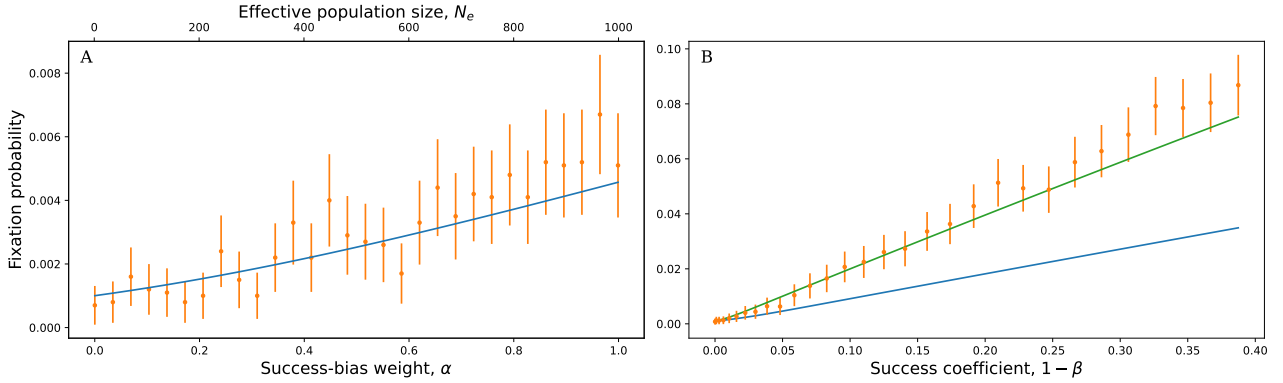

Figure S7: Fixation probability in a changing environment, $k > l$. (A) Fixation probability decreases with the success-bias weight (bottom x-axis) and effective population size (top x-axis). The approximation (blue; eq. (23)) agrees with simulation results (orange). (B) Fixation probability increases with the success coefficient, β . When success bias is large ($1 - \beta > 0.1$), simulation results (orange) are underestimated by the changing environment approximation (blue; eq. (23)). With even larger success bias ($1 - \beta > 0.35$), even the constant environment approximation (green; eq. (19)) slightly underestimates simulation results, likely because the diffusion equation approximation assumes weak 'selection'. Markers show average of 10,000 simulations, error bars show 75% (panel A) and 95% (panel B) confidence intervals. Here, population size is $N = 1,000$; In panel A, $A = 0.9$, $\hat{A} = 1$ ($1 - \beta = s = 0.005$), $k = 80$, and $l = 20$; In panel B, $0.01 < A < 0.99$, and $\hat{A} = 1$, which determines $1 - \beta$ via $\beta = \beta(A)/\beta(\hat{A})$ and eq. (5), $k = 80$, and $l = 20$, $\alpha = 0.1$;
